In multicellular animals, physiological regulatory systems require information and cell-to-cell communication. Most intercellular communication is by means of chemical signals that bind to receptors, as described in [Chapter 7](#). Some types of chemical signals discussed in other chapters include growth factors, morphogens, and cytokines. In future chapters you will learn about chemical signals used by the nervous system called neurotransmitters. Each of these examples involves a chemical message secreted by cells and received by other cells (target cells) that have appropriate receptors. These four classes of chemical signals are named according to the types of actions they have: growth factors influence cell division, morphogens influence developmental processes, cytokines control immune system cells, and neurotransmitters enable nerve cells to communicate with each other and with target cells such as muscles. In this chapter we cover another broad class of chemical signals called [endocrines](#), which are secreted by epithelial cells directly into the extracellular fluid (ECF; see [Key Concept 39.2](#)). From the ECF, endocrines can diffuse locally and also into the blood, where they circulate throughout the body.

endocrines Chemical signals released by cells that enter the blood and affect cells anywhere in the body that have appropriate receptors. Also known as hormones.

focus your learning

Hormones affect target cells that have appropriate receptors.

Hormones stimulate signal transduction pathways in target cells either by binding to specific receptors on cell surfaces or by diffusing through the cell membrane to bind to internal receptors.

Different target cells can respond to the same hormone in different ways depending on the signal transduction pathway stimulated.

Intercellular chemical signaling mechanisms evolved early in the evolutionary history of multicellular animals.

There are multiple chemical communication systems in the body

Some analogies might help differentiate how chemical signaling in the immune, nervous, and endocrine informational systems works. The immune system (the topic of [Chapter 42](#)) operates like an army of private security guards. Immune system cells make their rounds of the body, and if they detect a security breach, they sound their alarms—cytokines—that activate the body's defenses. The nervous system (see [Chapters 44-46](#)) operates like a landline telephone system, with a central integration and command center that sends signals along specific wires to specific receivers. The endocrine system is more like a radio, television, or cell-phone system, broadcasting signals that can be picked up by anyone who has an appropriate receiver that is turned on and tuned in. Some endocrine signals are weak like those of a walkie-talkie and are

picked up only locally, but others are strong like those of a major broadcast station and reach distant parts of the body. In all cases, the signals are received only by cells that have appropriate receptors, and the responses are determined by the receiving cell's internal signal transduction machinery.

Endocrine signaling can act locally or at a distance

Endocrine signals that enter the blood are called **hormones** (from a Greek word meaning to excite, arouse, or stimulate). Hormones activate target cells wherever they occur in the body (**Figure 40.1A**). You probably are familiar with several hormones, such as testosterone, estrogen, adrenaline (also called epinephrine), and insulin. Those molecules are well known, as are their sites of release and their actions.

hormone (hore' mone) [Gk. *hormon*: to excite, stimulate] A chemical signal produced in minute amounts at one site in a multicellular organism and transported to another site where it acts on target cells.

(A) Signals that act at a distance

(B) Signals that act locally

Figure 40.1 Chemical Signaling Systems (A) Hormones are distributed throughout the body in the bloodstream. **(B)** Paracrine and autocrine signals diffuse locally in the extracellular fluid. Paracrine signals influence nearby cells, and autocrine signals influence the same cells that release them.

Some endocrine signals are released in such tiny quantities, or are so rapidly inactivated by enzymes or taken up so efficiently by local cells, that they never diffuse into the blood in sufficient amounts to act on distant cells (**Figure 40.1B**). Because these signals affect only target cells near their release site, they are called **paracrine** (*para*, “near”). An example of a paracrine signal is histamine, one of the mediators of inflammation. The most local action an endocrine signal can have is when it binds to receptors on or in the same cell that secreted it. An **autocrine** signal is so named because it influences the cell that secreted it. Hormones and paracrine signals can have autocrine functions as a means of providing negative feedback to control their own rates of secretion.

paracrine [Gk. *para*: near] Pertaining to a chemical signal, such as a hormone, that acts locally, near the site of its secretion. (Contrast with autocrine.)

autocrine A chemical signal that binds to and affects the cell that makes it. (Contrast with paracrine.)

Some endocrine cells exist as single cells within a tissue. Hormones of the digestive tract, for example, are secreted by isolated endocrine cells in the walls of the stomach and small intestine. Many hormones are secreted by aggregations of endocrine cells in secretory organs called **endocrine glands**. A single endocrine gland may secrete multiple hormones. Be sure you don't confuse endocrine glands with **exocrine glands**. Endocrine glands secrete hormones within the body, whereas exocrine glands secrete substances through ducts to the outside of the body (sweat glands and salivary glands are examples).

endocrine gland (en' doh krin) [Gk. *endo*: within + *krinein*: to separate] An aggregation of secretory cells that secretes hormones into the blood. The endocrine system consists of all

endocrine cells and endocrine glands in the body that produce and release hormones. (Contrast with exocrine gland.)

exocrine gland (eks' oh krin) [Gk. *exo*: outside + *krinein*: to separate] Any gland, such as a salivary gland, that secretes to the outside of the body or into the gut. (Contrast with endocrine gland.)

Two other categories of chemical signals are neuroendocrines or **neurohormones** that are secreted by nerve cells and enter the circulation, and the **pheromones** that are released from the body of an animal to influence the behavior and physiology of other animals in its vicinity. We will discuss pheromones in [Chapter 52](#).

neurohormone A chemical signal produced and released by neurons that subsequently acts as a hormone.

pheromone (feer' o mone) [Gk. *pheros*: carry + *hormon*: excite, arouse] A chemical substance used in communication between organisms of the same species.

Hormones are divided into three chemical groups

There is enormous diversity in the chemical structure of hormones, but by and large they can be classified into three groups:

- **Peptide** and **protein hormones** make up the majority of hormones. A peptide consists of 2 or more amino acids, and a protein is defined as having 50 or more amino acids. Insulin is therefore a small protein hormone (**Figure 40.2A**). Peptide and protein hormones are water-soluble and thus easily transported in the blood. They can be packaged in vesicles within the cells that make them, and then released by exocytosis.

protein hormones Large hormone molecules made up of chains of generally greater than 50 amino acids; encoded by genes and produced by translation.

(A) Protein hormone**(B) Steroid hormones****(C) Amine hormones**

Figure 40.2 Three Classes of Hormones (A) The largest hormone molecules are peptides and proteins. An example of a protein hormone is the pancreatic hormone insulin. (B) Steroid hormones are modified from cholesterol molecules. They include the corticosteroids produced by the adrenal gland and the sex steroids produced primarily by the gonads. (C) Amine hormones are tiny molecules synthesized from a single amino acid. Both epinephrine and thyroxine are synthesized from tyrosine units, but thyroxine is lipid-soluble and epinephrine is water-soluble. Their modes of release and transport and the locations of their receptors differ accordingly.

Steroid hormones (such as estrogen and testosterone) are synthesized from cholesterol (Figure 40.2B), are lipid-soluble, and pass easily through cell membranes. Steroid hormones diffuse out of the cells that make them and are usually bound to carrier molecules in the blood.

steroid hormones Steroid molecules that circulate in the blood and effect cells with appropriate receptors. Examples are testosterone and estrogen.

Amine hormones are mostly synthesized from the amino acid tyrosine (thyroxine is one example; Figure 40.2C). Some amine hormones are water-soluble and others are lipid-soluble; their modes of release differ accordingly.

amine hormones Small hormone molecules synthesized from single amino acids (e.g., thyroxine and epinephrine).

Hormone action is mediated by receptors on or within their target cells

Water-soluble hormones cannot pass readily through cell membranes; instead they bind to

receptors on the surfaces of target cells.

These receptors are large transmembrane glycoprotein complexes with three domains:

- . A binding domain that projects outside the cell membrane
- . A transmembrane domain that anchors the receptor in the membrane
- . A cytoplasmic domain that extends into the cytoplasm of the cell

When a hormone binds to the binding domain, the cytoplasmic domain initiates the target cell's response, usually through second messengers. Second messengers activate a cascade of intracellular events, eventually activating protein kinases or protein phosphatases (see [Figures 7.6](#) and [7.7](#)). In most cases these protein kinases and phosphatases activate or inactivate enzymes in the cytoplasm that lead to the cell's response, but the signaling cascade initiated by the receptor can also generate signals that enter the nucleus and alter gene expression (see [Figure 7.10](#)).

Lipid-soluble hormones can diffuse through cell membranes, and therefore their receptors are usually inside cells, in either the cytoplasm or the nucleus. There are also some membrane-bound receptors for lipid-soluble hormones, but they are the exception rather than the rule. In most cases, the complex formed by the lipid-soluble hormone and its receptor acts by altering gene expression in the cell's nucleus (see [Figure 7.8](#)).

Hormone action depends on the nature of the target cell and its receptors

Wherever a hormone encounters a cell with an appropriate receptor, it can bind to that receptor and trigger a response. The nature of the response depends on the signal transduction pathways of the responding cell. Therefore the same hormone can cause different responses in different types of cells.

Consider the amine hormone [epinephrine](#), and the closely related amine hormone as well as neurotransmitter [norepinephrine](#). Both of these molecules are involved in the well-known **fight-or-flight response** ([Figure 40.3](#)). Suppose you are walking in the forest and almost step on a rattlesnake. You jump back, your heart starts to thump, and protective reactions are set in motion. The jump and the heart thumping are driven by your rapidly responding sympathetic nervous system (see [Figure 46.8](#)) which uses norepinephrine to signal target cells. Simultaneously with these muscular responses, your sympathetic nervous system stimulates endocrine cells in the adrenal glands just above your kidneys to secrete both epinephrine and norepinephrine. These hormones rapidly diffuse into your blood and circulate around your body, activating the many components of the fight-or-flight response.

epinephrine (ep i nef' rin) [Gk. *epi*: over + *nephros*: kidney] The "fight or flight" hormone produced by the medulla of the adrenal gland; it also functions as a neurotransmitter. Also known as adrenaline.

norepinephrine A neurotransmitter found in the central nervous system and also at the postganglionic nerve endings of the sympathetic nervous system. Also called noradrenaline.

Figure 40.3 The Fight-or-Flight Response The brain of a person suddenly faced with a threatening situation sends a signal to the adrenal glands, which almost instantaneously release the hormones epinephrine and norepinephrine. Epinephrine and norepinephrine circulate around the body and induce the various components of the fight-or-flight response in different tissues.

Epinephrine and norepinephrine bind to receptors in your heart, causing a faster and stronger heartbeat. Your heart is now pumping more blood. Epinephrine also binds to receptors in certain

blood vessels. By causing constriction of blood vessels supplying your skin, kidneys, and digestive tract (digesting lunch can wait!), the hormone diverts more blood to the muscles needed for your escape from danger.

Epinephrine binds to cells in the liver, stimulating them to break down glycogen and release glucose into the blood as a quick energy supply (see [Figure 7.15](#)). In fatty tissue, epinephrine stimulates the breakdown of fats to yield fatty acids—another source of energy. These are just some of the actions triggered by one hormone. In each case the cellular response depends on the cell's receptors, its associated intracellular signaling cascade, and the mechanisms activated by that signaling cascade. All of the diverse cellular responses activated by epinephrine and norepinephrine increase your chances of surviving a dangerous situation.

Hormone structure is conserved through evolution, but functions change

Intercellular chemical signaling was critical for the evolution of multicellularity, so hormones have a long evolutionary history. The least complex of the multicellular animals—the sponges—do not have nervous systems, but they do have intercellular chemical communication. Studying the evolution of hormonal signaling reveals an interesting generalization: the signal molecules themselves are highly conserved. We find the same chemical compounds over broad groups of organisms, although their functions may differ. As organisms have evolved to occupy different environments and have different lifestyles, the same hormone-receptor systems have diversified to serve different functions. A good example of this evolutionary diversification is the hormone prolactin, described in [Figure 40.4](#). The name prolactin reflects the role this hormone plays in mammals to stimulate the growth of mammary glands and the production of milk. Mammary glands are unique to mammals, but we find prolactin in all vertebrate groups—and in all cases it is involved in some way in reproduction.

Fishes

Prolactin is required for osmoregulation in freshwater species. In saltwater species that return to fresh water to spawn (e.g., salmon), prolactin production in adults may play a role in generating the drive to return to natal streams.

Amphibians

In some species, prolactin creates a "water drive" that returns adults to breeding locations. Stimulates oviduct development and production of egg jelly in females. In some species, controls development of sexual characteristics.

Mammals

In females, prolactin stimulates growth of the mammary glands and milk production. In humans, it is responsible for the sensation of sexual gratification as well as the male refractory period following sexual intercourse.

Birds

In some species, prolactin stimulates nesting activity, incubation behavior, and parental care in both sexes. In pigeons and doves it stimulates production of crop milk to nurture the young nestlings.

Figure 40.4 Prolactin's Structure Is Conserved, but Its Functions Have Evolved

The hormone prolactin is found in all vertebrate groups and has a long evolutionary history. Its probable function in early vertebrates was in regulating the body's salt and water balance (osmoregulation). It maintains this function in some species, and has evolved in others to control a number of physiological processes, most of which are associated with reproduction.

The list of hormones known to exist is long and growing longer (as shown by the recent discovery of irisin). To make the subject manageable, we will focus primarily on the endocrine system of mammals. [Figure 40.5](#) presents the human endocrine glands and most of the hormones that are discussed in this and subsequent chapters.

Figure 40.5 The Endocrine System of Humans Cells that produce and secrete hormones may be organized into discrete endocrine glands, or they may be embedded in the tissues of other organs, such as the digestive tract or kidneys. The hypothalamus is part of the brain, but it includes cells that secrete neurohormones into the extracellular fluid.

Activity 40.1 The Human Endocrine Glands www.Life11e.com/ac40.1

40.1 recap

Endocrine signals initiate responses in target cells that vary depending on the signal transduction pathways of the responding cell. Autocrines and paracrines act locally. Hormones are chemical signals released by endocrine cells into the extracellular fluid, where they diffuse into the blood and travel to distant target cells. The receptors for water-soluble hormones are on the surfaces of target cells; receptors for most lipid-soluble hormones are inside the target cells. The chemical structures of signal molecules have been highly conserved over evolutionary time, but the chemical compounds serve different functions in different organisms.

learning outcomes

You should be able to:

- Describe the structural feature of hormones that determines whether they act on surface or cytoplasmic receptors.
 - Explain how different target cells in the body can respond differently to a single hormone.
 - Discuss scientific thinking about the evolutionary history of hormones in multicellular animals.
-

1. Why are the effects of epinephrine more rapid than the effects of estrogen?
 2. Why is the presence of a particular hormone in two species not an indication of the closeness of their evolutionary relationship?
 3. How can a single hormone have two different effects in the same species?
-

The advantage of hormone signals is that they can originate from a localized source but reach cells in all areas of the body and coordinate their activities. The disadvantage of hormones is that they are relatively slow in delivering and in terminating their messages. Thus they are not good for communicating rapidly changing information. In contrast, the nervous system sends messages to specific target cells, and its messages are rapid and can be turned off quickly. In addition, the nervous system has access to a great diversity of both external and internal information that indicates the state of the body and threats to homeostasis. The different characteristics of each of these informational systems make it advantageous for them to work together.

40.2 The Endocrine System and Nervous System Work Together

The nervous system and the endocrine system control and regulate virtually all physiological and behavioral mechanisms that contribute to homeostasis, survival, and reproductive success. Challenges to an organism usually trigger both physiological and behavioral responses, as we saw with respect to thermoregulation in [Chapter 39](#) and also with the fight-or-flight reactions shown in [Figure 40.3](#). Therefore the endocrine and nervous systems must work together in an integrated fashion, and indeed they do. The nervous system receives an enormous amount of information from the body and from the environment. That information is critical for maintenance of homeostasis, survival, and reproductive success. The nervous system controls many tissue and organ functions as well as behavior. It is therefore not surprising that the nervous system regulates many endocrine functions. Conversely, hormones circulate to the nervous system, providing feedback information used in regulation. Hormones reaching the brain also stimulate behaviors that contribute to the health and well being of an organism.

focus your learning

Oxytocin and vasopressin are produced in the hypothalamus and secreted from nerve terminals in the posterior pituitary.

The anterior pituitary produces four tropic hormones plus growth hormone, prolactin, and melanocyte stimulating hormone.

The release of hormones from the anterior pituitary is controlled by hypothalamic hormones transported to the pituitary in portal vessels.

Regulation involves short-loop and long-loop negative feedback.

The pituitary is an interface between the nervous and endocrine systems

The pituitary gland sits in a depression at the bottom of the skull, just over the back of the roof of the mouth ([Figure 40.6](#)). It is attached by a stalk to the hypothalamus, which is involved in many physiological regulatory systems such as that of thermoregulation (see [Key Concept 39.5](#)). Through its close connection with the hypothalamus, the pituitary serves as the interface between the nervous system and the endocrine system and is involved in the hormonal control of many physiological processes.

Figure 40.6 The Posterior Pituitary Releases Neurohormones Neurons in the hypothalamus produce two peptide neurohormones — antidiuretic hormone and oxytocin—which are stored in and released by nerve endings in the posterior pituitary.

The pituitary has two parts with different developmental origins. The **anterior pituitary** originates as an outpocketing of the roof of the embryonic mouth cavity. The **posterior pituitary** originates as an outpocketing of the floor of the developing brain. Thus the anterior pituitary originates from gut epithelial tissue and the posterior pituitary from neural tissue. Both parts interact with the nervous system but in different ways. The anterior pituitary is controlled by hypothalamic neurohormones that reach the anterior pituitary via the blood. The posterior pituitary contains long extensions of hypothalamic neurons that release their neurohormones in the posterior pituitary.

anterior pituitary The portion of the vertebrate pituitary gland that derives from gut epithelium. Produces trophic hormones.

posterior pituitary A portion of the pituitary gland derived from neural tissue; involved in the storage and release of antidiuretic hormone and oxytocin.

Animation 40.1 **The Hypothalamic-Pituitary-Endocrine Axis** www.Life11e.com/a40.1

THE POSTERIOR PITUITARY

The long hypothalamic neuron extensions into the posterior pituitary are called **axons**. The terminals of these axons in the posterior pituitary contain vesicles of neurohormones—either antidiuretic hormone or oxytocin. When these hypothalamic neurons are activated, they fire electrical signals (* **action potentials**) that travel down the axon and cause the release of the neurohormones (see [Figure 40.6](#)).

axon [Gk. axle] The process (branching structure) of a neuron that conducts action potentials away from the cell body. (See *also* dendrites.)

The main action of **antidiuretic hormone (ADH)** in mammals and birds is to increase the amount of water conserved by the kidneys. When ADH secretion is high, the kidneys produce only a small volume of highly concentrated urine. When ADH secretion is low, the kidneys produce a large volume of dilute urine. The posterior pituitary increases its release of ADH when blood pressure falls or the blood becomes too salty. ADH is also known as **vasopressin** because at high concentrations it causes the constriction of peripheral blood vessels as a means of elevating blood pressure.

antidiuretic hormone (ADH) See vasopressin.

vasopressin A hormone that promotes water reabsorption by the kidney. Produced by neurons in the hypothalamus and released from nerve terminals in the posterior pituitary. Also called antidiuretic hormone or ADH.

The hormone **oxytocin** is released from the posterior pituitary when a woman is about to give birth. Oxytocin stimulates contractions of the uterine muscles, resulting in the delivery of the baby. Oxytocin also brings about the flow of milk from the mother's breasts. The baby's suckling stimulates neurons in the mother's brain that cause the secretion of oxytocin. Even the crying of her baby can cause a nursing mother to secrete oxytocin, resulting in the release of breast milk—a good example of how the nervous system integrates information that regulates hormonally mediated processes.

oxytocin A hormone released by the posterior pituitary that promotes social bonding.

THE ANTERIOR PITUITARY

The anterior pituitary produces and releases into the circulation four peptide and protein hormones that act as **tropic hormones**, meaning they control the activities of other endocrine glands. These four tropic hormones are thyrotropin (thyroid-stimulating hormone), luteinizing hormone (LH), follicle-stimulating hormone (FSH), and adrenocorticotropin (ACTH). Each is produced by a different type of pituitary cell. We will say more about these tropic hormones

when we describe their target glands—the thyroid, testes, ovaries, and adrenal cortex—later in this chapter and in [Chapter 42](#). Other peptide and protein hormones produced by the anterior pituitary are prolactin (see [Figure 40.4](#)), growth hormone, enkephalins and endorphins, and melanocyte stimulating hormone (MSH).

tropic hormones Hormones produced by the anterior pituitary that control the secretion of hormones by other endocrine glands.

[Growth hormone \(GH\)](#) acts on a wide variety of tissues to promote growth and development. One of its important effects is to stimulate cells to take up amino acids. Growth hormone also promotes growth by stimulating the liver to produce chemical signals that stimulate the growth of bone and cartilage. Overproduction of GH in children causes gigantism; affected individuals may grow to nearly 8 feet tall. Underproduction of GH results in pituitary dwarfism, in which individuals fail to reach normal adult height.

growth hormone (GH) A peptide hormone released by the anterior pituitary that stimulates many anabolic processes.

[Endorphins](#) and [enkephalins](#) are the body's natural painkillers. In the brain, these molecules act as neurotransmitters in pathways that control pain. Their production in the anterior pituitary is normally quite small and probably has little significant effect.

endorphins Molecules in the mammalian brain that act as neurotransmitters in pathways that control pain.

enkephalins Molecules in the mammalian brain that act as neurotransmitters in pathways that control pain.

[Melanocyte-stimulating hormone \(MSH\)](#) stimulates the production of the pigment melanin in skin and hair. MSH is produced by a thin layer of cells between the anterior and posterior pituitary that is sometimes called the intermediate lobe of the pituitary.

melanocyte-stimulating hormone (MSH) A pituitary peptide hormone that stimulates melanocytes to produce the pigment melanin.

Hypothalamic neurohormones control the anterior pituitary

Hypothalamic neurons do not extend into the anterior pituitary as they do into the posterior pituitary. So how do the neurohormones produced by hypothalamic neurons reach the anterior pituitary cells they control? The pituitary is connected to the brain by the pituitary stalk (**Focus: Key Figure 40.7**). Within that stalk are hypothalamic-pituitary [portal blood vessels](#). The hypothalamic cells secrete neurohormones at the bottom of the hypothalamus where the stalk begins. The neurohormones diffuse into the portal blood vessels that begin there, and are carried in the blood to where the portal vessels end in the anterior pituitary. Hypothalamic neurohormones are released in such tiny amounts that they were only hypothesized to exist before the technology was developed to isolate and characterize their structure.

portal blood vessels Blood vessels that begin and end in capillary beds.

focus: key figure

Figure 40.7 The Anterior Pituitary Is Controlled by the Hypothalamus Cells of the anterior pituitary produce tropic hormones that control other endocrine glands, as well as several other peptide and protein hormones. These cells are controlled by neurohormones produced in the hypothalamus and are called releasing or release-inhibiting hormones. These neurohormones are delivered through portal blood vessels that run between the hypothalamus and the anterior pituitary through the pituitary stalk.

Q: Melanocyte stimulating hormone (MSH) is an anterior pituitary hormone (not shown in [Figure 40.7A](#)). When anterior pituitary cells are grown in culture they release MSH into the medium. If extracts of the hypothalamus are added to the medium, the release of MSH decreases. What do these results tell you about the hypothalamic control over MSH producing cells?

In the 1960s two large teams of scientists led by Roger Guillemin and Andrew Schally initiated the search for these hypothalamic secretions. Massive numbers of hypothalami from pigs and sheep were collected from slaughterhouses and shipped to laboratories. One extraction effort began with the hypothalami from 270,000 sheep and yielded only 1 mg of purified [thyrotropin-releasing hormone \(TRH\)](#). TRH was the first hypothalamic release-stimulating hormone to be isolated and characterized. It turned out to be a simple tripeptide consisting of glutamine, histidine, and proline. It causes certain anterior pituitary cells to release the tropic hormone thyrotropin, which in turn stimulates the activity of the thyroid gland.

thyrotropin-releasing hormone (TRH) Hormone produced by the hypothalamus that stimulates the anterior pituitary to release thyrotropin.

Soon after discovering TRH, Guillemin's and Schally's teams identified [gonadotropin-releasing hormone \(GnRH\)](#), which stimulates certain anterior pituitary cells to release the tropic hormones that control the activity of the gonads (the ovaries and the testes). For these discoveries, Guillemin and Schally shared the 1977 Nobel Prize in Medicine with Rosalyn Yalow, who invented the technique of radioimmunoassay, which made possible the measurement of miniscule amounts of specific molecules such as releasing hormones.

gonadotropin-releasing hormone (GnRH) Hormone produced by the hypothalamus that stimulates the anterior pituitary to secrete gonadotropins.

Many other hypothalamic neurohormones, including both releasing and release-inhibiting hormones, are now known. The major hypothalamic neurohormones that control anterior pituitary function are listed in [Figure 40.7](#).

Negative feedback loops regulate hormone secretion

In addition to being controlled by hypothalamic releasing and release-inhibiting hormones, the endocrine cells of the anterior pituitary are also under direct and indirect negative feedback control by the hormones of the target glands they stimulate (see [Figure 40.7](#)). For example, cortisol, produced by the adrenal gland in response to ACTH secreted by the anterior pituitary, reaches the pituitary in the circulating blood and inhibits further release of ACTH. Cortisol also acts as a negative feedback signal to the hypothalamus, inhibiting the release of corticotropin-releasing hormone (CRH). Because cortisol is the final hormone released in this chain of interacting structures called the hypothalamic-pituitary-adrenal axis, its feedback actions are called long-loop negative feedback. In this system, the tropic hormone ACTH also exerts negative feedback control on the hypothalamic cells that produce the corresponding releasing hormone (CRH). This action is called short-loop negative feedback because of the proximity of the pituitary and the hypothalamus.

Hormones influence the nervous system

Hormones have more influences on the nervous system than simply being negative feedback

signals controlling their own secretion. For example, the posterior pituitary hormone oxytocin, which plays a role in the birth process and in stimulating the flow of milk from the breasts, also has a strong behavioral effect in promoting bonding (see the story that opens [Chapter 7](#)). If oxytocin release is experimentally blocked, mammalian mothers, from rats to sheep, will reject their newborn offspring, but if a virgin rat is given a dose of oxytocin, she will adopt strange pups as if they were her own. Oxytocin promotes pair bonding in a variety of animals. In humans, oxytocin secretion rises with intimate sexual contact, and it has been nicknamed the “cuddle hormone.” Experiments using games involving financial exchanges have shown that puffs of oxytocin applied to the nostrils raise the level of trust between players. Thus circulating hormones can have a strong influence on behavior. Another example is the effects of sex hormones, which we will discuss in [Key Concept 53.3](#).

Recent investigations involving the hormone irisin that was presented at the beginning of this chapter reveal that this same molecule may mediate effects of exercise on the brain. Many experiments have shown that exercise improves cognitive functions. Beneficial effects of exercise have been shown especially for a part of the brain called the hippocampus that is involved in learning and memory. These effects include the production of new brain cells, increased blood flow, and changes in the structures supporting communication between brain cells. It had been established that one molecular factor involved in the beneficial effects of exercise on the hippocampus is BDNF, which stands for brain-derived neurotrophic factor. How does exercise mediate the release of BDNF in the brain? **Investigating Life: How Could Irisin Mediate the Benefits of Exercise on Cognition?** explores this interesting question.

investigatinglife How Could Irisin Mediate the Benefits of Exercise on Cognition?

experiment

Original Paper: Wrann, C. D. et al. 2013. Exercise induces hippocampal BDNF through a PGC-1 α /FNDC5 pathway. *Cell Metabolism* 18: 649–659.

Irisin secreted by exercising muscle is cleaved from a protein called FNDC5, and FNDC5 expression is controlled by the transcription factor PGC-1 α . Irisin then circulates in the blood, but because of the blood–brain barrier (see Key Concept 44.1), it is unlikely to reach brain structures such as the hippocampus where it could enhance cognition. However, could irisin also be expressed in the brain? If so, exercise should result in similar changes in expression of FNDC5 and its transcription factor PGC-1 α in the hippocampus as it does in skeletal muscle. First, we need to show in our experimental system and with our assays that exercise induces expression of PGC-1 α and FNDC5 in exercising muscle. Then we can use the same experimental system to investigate expression in the hippocampus.

HYPOTHESIS ▶ Endurance exercise results in increased expression of PGC-1 α and FNDC5 in skeletal muscle.

METHOD

1. Have one group of mice exercise on running wheels for 30 days and a control group that does not, $N = 10$ for each group.
2. At the end of 30 days, measure PGC-1 α and FNDC5 mRNA levels in leg muscle of both groups of mice.
3. Plot the data for each variable (FNDC5 and PGC-1 α) for the exercised and control mice, and use an un-paired t -test (see Appendix B) to evaluate the significance of the results.

RESULTS Error bars indicate ± 1 standard deviation.

CONCLUSION ▶ Relative levels of FNDC5 mRNA were significantly higher in the exercised than in the non-exercised mice ($P < 0.001$). Relative levels of PGC-1 α mRNA also were significantly higher in the exercised than in the non-exercised mice ($P < 0.01$).

work with the data

Similar measurements of expression of FNDC5 and PGC-1 α mRNAs were made from the hippocampus of the exercised and the non-exercised mice. Again, $N = 10$ for each group. The results are shown in the table.

FNDC5		PGC-1 α	
Control	Exercised	Control	Exercised
1.02	1.33	1.22	1.23
1.10	1.24	0.84	1.09
0.92	1.68	1.06	1.35
0.93	1.30	1.26	1.18
1.21	1.34	1.04	1.40
0.93	1.33	1.12	1.18
0.96	1.50	1.04	1.46
1.01	1.29	1.09	1.19
1.00	1.44	1.02	1.54
0.97	1.41	0.54	1.16

QUESTIONS

1. Plot the data as was done for the leg skeletal muscle results. Then you can apply the same analysis methods to these data that were applied to the leg muscle data in the preceding experiment. Did exercise have a significant effect on FNDC5 and PGC-1 α expression in the hippocampus?
2. The neurotrophic factor BDNF is a secreted protein that plays important roles in neural changes associated with learning and memory. How would you determine if the exercise protocol induced a significant increase in BDNF expression in the hippocampus, assuming you have an assay for BDNF?
3. How could you determine if a noted increase in the expression of FNDC5 in the hippocampus is sufficient for an increased expression of BDNF in the hippocampus? Assume you can culture hippocampal neurons so that the expression of FNDC5 is stimulated or suppressed.

A similar **work with the data** exercise may be assigned in **LaunchPad**.

40.2 recap

The pituitary is the interface between the nervous system and the endocrine system. The posterior pituitary releases two neurohormones, antidiuretic hormone (ADH) and oxytocin. The anterior pituitary, under the control of other neurohormones from the hypothalamus, releases four tropic hormones that control other endocrine glands. In addition, the anterior pituitary produces and releases five other hormones that act directly on non-endocrine tissues. The hypothalamus and pituitary are under negative feedback control by the hormones of their target glands.

learning outcomes

You should be able to:

- Describe the relationships between the hypothalamus and the pituitary gland.
- Explain developmental origins of the anterior pituitary and the posterior pituitary.
- Explain how a negative feedback loop controls hormone secretion.

1. Provide a developmental explanation of why posterior pituitary hormones are released from neurons and anterior pituitary hormones are released from epithelial cells.
2. How do hypothalamic neurons control the release of hormones from the anterior pituitary?
3. Explain what is meant by negative feedback in the hypothalamic control of endocrine function.

The hypothalamic and pituitary hormones and some of the endocrine glands they control are easy to conceptualize because they share common features in how they are organized and function. But the entire list of hormones is highly diverse, making generalizations difficult. We cannot consider all of the hormones in this chapter. Instead, we focus on hormones that have some common functions—one of which is the coordination of developmental processes.

***connect the concepts** As described in [Key Concept 45.2](#), action potentials are sudden and transient electric signals generated by voltage-gated ion channels in the cell membrane of the axon. These signals travel rapidly along axons, and their arrival at the axon terminals initiates the release of neurotransmitters.

40.3 Hormones Play Important Roles in Development

The development of an animal from a fertilized egg requires the coordination of processes throughout the body. Imagine the problems that would arise if growth of the body were not symmetrical, or if the growth of organ systems did not match the demands placed on them by the growing body. Because hormones circulate in the blood to all parts of the body, they are ideal signals for integrating and coordinating the many diverse processes involved in development.

focus your learning

Classic experiments revealed that hormones control insect metamorphosis.

Vertebrate sexual development is controlled by steroid hormones.

Human puberty results from a change in sensitivity of the hypothalamus to negative feedback.

Insect development consists of either complete or incomplete metamorphosis

The changes that occur in a developing insect can be dramatic and involve major changes in body form. Insects such as bees and butterflies undergo a developmental process called **complete metamorphosis**. Starting out as a caterpillar (a larva), a butterfly feeds voraciously and goes through a series of growth stages called **instars**, which are separated by molts. The last instar builds a cocoon and enters into a quiescent, transformative state called a pupa. The tissues of the pupa are extensively remodeled to form the adult body, which is entirely different from that of the larva. The larval butterfly crawls and eats vegetation; the adult butterfly flies and eats flower nectar. Many other species of insects undergo **incomplete metamorphosis**, which involves less extreme changes of body form. These insects also go through a series of instars, getting bigger with each molt, but the last juvenile instar simply molts into the adult form with all of the essential adult body parts. Molting involves shedding the skin, or in many cases the rigid exoskeletons, and therefore requires coordination of cellular processes in the entire epidermis of the animal. Both complete and incomplete ***metamorphosis** require integrated processes in all parts of the insect body.

complete metamorphosis A change of state during the life cycle of an organism in which the body is almost completely rebuilt to produce an individual with a very different body form. Characteristic of insects such as butterflies, moths, beetles, ants, wasps, and flies.

instar (in' star) An immature stage of an insect between molts.

incomplete metamorphosis Insect development in which changes between instars are gradual. (Contrast with direct development, complete metamorphosis.)

Experiments on insect development revealed hormonal signaling systems

Pioneering experiments of hormonal action and control in insects were done on the bloodsucking bug *Rhodnius prolixus*, which undergoes incomplete metamorphosis. Newly hatched *Rhodnius* lack certain adult features and molt five times before developing into a

mature adult. A blood meal triggers each episode of molting and growth. *Rhodnius* is an amazingly hardy experimental animal—it survives for quite a long time after its head is cut off. If decapitated within an hour after a blood meal, *Rhodnius* can survive for up to a year, but it never molts. If decapitated a week after its blood meal, however, it does molt into an adult.

This observation suggested that molting was triggered by some substance slowly diffusing from the head. To test this hypothesis, two decapitated bugs—one soon after a blood meal and one a week after a blood meal—were connected together with a glass tube that allowed body fluids to cross between the two bugs. Both molted into adults proving that a diffusible substance from the bug's head triggered molting.

Since those pioneering experiments on *Rhodnius*, the chemical nature of the diffusible substances (hormones) controlling molting in arthropods have been identified and their functions described.

Three hormones regulate molting and maturation in arthropods

An arthropod's nervous system receives various types of information about the environment (e.g., day length, temperature, social cues, and nutrition) that help determine the optimal timing for the stages of growth and development. When conditions are right, the brain signals the [prothoracic gland](#) to produce the hormones that orchestrate physiological processes involved in development and molting.

prothoracic gland A gland in insects that secretes the molting hormone ecdysone.

PTTH AND ECDYSONE

Two hormones, **prothoracicotropic hormone (PTTH)** and **ecdysone**, work in sequence to regulate molting in arthropods. Cells in the brain produce PTTH, which is why it has also been called “brain hormone.” PTTH is transported to and stored in paired structures called the **corpora cardiaca** attached to the brain (**Figure 40.8**). After appropriate stimulation (which for *Rhodnius* is a blood meal), PTTH is released and diffuses through the extracellular fluid to an endocrine gland, the prothoracic gland. PTTH stimulates the prothoracic gland to secrete the hormone ecdysone. Ecdysone diffuses to target tissues and stimulates molting.

prothoracicotropic hormone (PTTH) An insect hormone that controls the prothoracic gland.

ecdysone (eck die' sone) [Gk. *ek*: out of + *dyo*: to clothe] In insects, a hormone that induces molting.

corpora cardiaca An insect endocrine gland that secretes PTTH.

Figure 40.8 Hormonal Control of Metamorphosis Three hormones control molting and metamorphosis in the silkworm moth *Hyalophora cecropia*.

 Animation 40.2 **Complete Metamorphosis** www.Life11e.com/a40.2

Ecdysone is a steroid hormone (see [Figure 40.2B](#)) and thus is related to the vertebrate hormones estrogen and testosterone (which also play roles in controlling growth and development). Ecdysone is lipid-soluble and readily passes through the cell membrane of its target cells (mostly cells of the epidermis). In the target cells, ecdysone binds to a receptor that induces expression of genes encoding enzymes involved in digesting the old cuticle and secreting a new one.

JUVENILE HORMONE

What determines whether an instar molts into another juvenile form or matures into an adult?

[Juvenile hormone](#) is a molecule that is released continuously from the corpora allata (structures that are attached to the [corpora cardiaca](#), which release PTTH). As long as juvenile hormone is present, *Rhodnius* molts into another juvenile instar. Normally *Rhodnius* stops producing juvenile hormone during the fifth instar and then molts into an adult.

juvenile hormone In insects, a hormone maintaining larval growth and preventing maturation or pupation.

corpora cardiaca An insect endocrine gland that secretes PTTH.

The role of juvenile hormone is more complex in insects that undergo complete metamorphosis. An example of complete metamorphosis is provided by the silkworm moth *Hyalophora cecropia* (see [Figure 40.8](#)). As long as juvenile hormone is present in high concentrations, larvae molt into larger larvae. When the level of juvenile hormone falls, larvae spin cocoons and molt into pupae. Because no juvenile hormone is produced in pupae, they molt into adults. Many modern pesticides use juvenile hormone analogs to prevent larvae developing into adults.

These cases of insect development show how just a few hormones can coordinate major developmental effects that involve very different cell types and tissues in the body. The hormonal signals reach all parts of the body simultaneously, and depending on the receptors on different cell types and the internal mechanisms driven by those receptors, the developmental processes are orchestrated.

Sex steroids control sexual development

Hormones also control many developmental processes in vertebrates. One example already mentioned in [Key Concept 40.2](#) is the influence that the anterior pituitary growth hormone has on growth.

Other examples are the hormones involved in sex development. The [gonads](#)—the testes of the male and the ovaries of the female—produce hormones as well as sperm and ova. The male steroid hormones are collectively called [androgens](#), and the dominant hormone is testosterone. The female steroids are [estrogens](#) and [progesterone](#). The dominant estrogen is estradiol, which is synthesized from testosterone. Males and females both synthesize testosterone, but females have an enzyme (aromatase) that converts testosterone to estradiol.

gonad (go' nad) [Gk. *gone*: seed] An organ that produces gametes in animals: either an ovary (female gonad) or testis (male gonad).

androgen (an' dro jen) Any of the several male sex steroids (most notably testosterone).

estrogen Any of several steroid sex hormones; produced chiefly by the ovaries in mammals.

progesterone [L. *pro*: favoring + *gestare*: to bear] A female sex hormone that maintains pregnancy.

 Media Clip 40.1 The Testosterone Factor www.Life11e.com/mc40.1

PHENOTYPIC SEX DETERMINATION

The sex steroids determine whether a mammalian embryo develops into a phenotypic female or male. In humans, the gonads of an early embryo are undifferentiated. Beginning in about the seventh week of development, the expression of genes on the Y chromosome of an XY individual normally causes the undifferentiated gonads to produce androgens. In response to androgens, the reproductive system develops the male phenotype. If no Y chromosome is present (i.e., the individual is genotype XX), androgens are not produced at this time and female structures develop (**Figure 40.09**). After birth, the sex steroids control the maturation of the reproductive organs and the development and maintenance of secondary sexual characteristics, such as breasts and facial hair.

Figure 40.9 Sex Steroids Direct the Development of Human Sex Organs The external sex organs of early human embryos are undifferentiated. Androgens promote the development of male sex organs. In the absence of androgens, female sex organs form.

Q: What do you think the effect of a mutation that results in nonfunctional androgen receptors would be?

Phenotypic sex determination provides a good example of the importance of receptors in hormonal control mechanisms. Individuals are occasionally born who because of a mutation do not have functional androgen receptors—a condition called androgen insensitivity syndrome. These individuals have an XY genotype and internal testes, but they develop the external body form and genitalia of a female.

PUBERTY

In juvenile humans, the sex steroids are produced at low levels. At puberty (around age 12 or

13), sex steroid production increases rapidly. Why does this sudden increase occur? In both juvenile and adult humans, the activities of the gonads are controlled by the anterior pituitary tropic hormones **luteinizing hormone (LH)** and **follicle-stimulating hormone (FSH)**, which together are the **gonadotropins**. The production of gonadotropins by the anterior pituitary is under the control of gonadotropin-releasing hormone (GnRH) produced by the hypothalamus (**Figure 40.10**). The production of GnRH is controlled by negative feedback from circulating sex steroids. Before puberty, the hypothalamus is very sensitive to that negative feedback signal, even though the circulating levels of sex steroids are low, and only low levels of GnRH are released. Puberty is initiated by a reduction in the sensitivity of hypothalamic GnRH-producing cells to negative feedback. As a result, GnRH production increases, stimulating increased production of gonadotropins and hence increased production of sex steroids.

luteinizing hormone (LH) A gonadotropin produced by the anterior pituitary that stimulates the gonads to produce sex hormones.

follicle-stimulating hormone (FSH) A gonadotropin produced by the anterior pituitary.

gonadotropin A trophic hormone that stimulates the gonads.

Figure 40.10 The Trigger for Puberty In a prepubertal individual, the gonads produce sex steroids in small quantities, and because the hypothalamus is highly sensitive to the negative feedback effects of those sex steroids, GnRH production is suppressed. A sudden decrease in the sensitivity of the hypothalamus to this feedback causes increased production of GnRH and the onset of puberty.

In females, increasing levels of LH and FSH at puberty stimulate the ovaries to increase their production of the female sex hormones. The increased circulating levels of these hormones stimulate the development of the traits of a sexually mature woman: enlarged breasts, vagina, and uterus; broadened hips; increased subcutaneous fat; pubic hair; onset of menstrual and

ovarian cycles (see [Figure 42.11](#)), and behavioral changes. In males, an increasing level of LH stimulates groups of cells in the testes to increase their synthesis of testosterone, which in turn initiates the physiological, anatomical, and behavioral changes associated with adolescence. The voice deepens, hair begins to grow on the face and body, and the testes and penis grow larger. Testosterone also stimulates bone and skeletal muscle growth. FSH in males stimulates production of sperm.

The roles that sex steroids play in adult sexual behavior and reproduction will be described in [Chapter 42](#).

40.3 recap

Hormones play major roles in development. Because they circulate throughout the body, they can simultaneously affect many cells and tissues, but in different ways depending on the receptors and intracellular pathways in those cells. Thus hormones can coordinate the complex sets of responses involved in development. Arthropod development involves complete or incomplete metamorphosis controlled by ecdysone, juvenile hormone, and prothoracicotropic hormone (PTTH). Human gonadal and phenotypic sex development is controlled by steroid hormones.

learning outcomes

You should be able to:

- Analyze observations made during experiments of arthropod development.
- Explain how an individual can have a male genotype but female body characteristics and genitalia.
- Explain the role of negative feedback in the timing of puberty in humans.

1. Why did decapitation of *Rhodnius* prevent molting when done 1 hour after feeding but not when done 1 week after feeding?
2. How can a person with an XY genotype develop with the phenotype of a female?
3. What is the role of negative feedback in the timing of puberty?

A common feature of the roles of hormones in development is that they coordinate the execution of events programmed into the genome. These functions have evolved to be rather stable in the face of changes in the internal and external environments. In contrast, hormones involved in maintaining homeostasis of the internal environment have evolved to be very sensitive to changes in the internal or external environment that could compromise homeostasis. We will look at some of these hormonal regulatory mechanisms in the next section.

***connect the concepts** Insect metamorphosis is described in more detail at the end of [Key Concept 32.4](#).

40.4 Hormones Regulate Metabolism and the Internal Environment

Hormones participate in regulation in all physiological systems. In this section we will examine a few major examples of hormonal action that are critical in regulating the internal environment. For simplicity we will focus on humans, but these systems are similar in all mammals.

focus your learning

The thyroid gland secretes the hormone thyroxine, which has multiple effects on metabolism, and calcitonin, which reduces blood calcium levels.

Calcitriol increases blood calcium.

Clusters of endocrine cells called islets of Langerhans in the pancreas secrete the hormones insulin, glucagon, and somatostatin.

The adrenal gland consists of the adrenal medulla, which secretes epinephrine and norepinephrine, and the adrenal cortex, which secretes steroid hormones.

Thyroxine stimulates many metabolic processes

Thyroxine is produced and secreted by the [thyroid gland](#). This gland wraps around the front of the windpipe (trachea) and expands into a lobe on either side (see [Figures 40.5](#) and [40.12](#)). There are two cell types in the thyroid gland, each of which produces a specific hormone. [Thyroxine](#) is produced by epithelial cells that make up round, colloid-containing structures called follicles ([Figure 40.11A](#)). [Calcitonin](#) is produced by cells in the spaces between the follicles and is involved in blood calcium regulation (which we will describe shortly).

thyroid gland [Gk. *thyreos*: door-shaped] A two-lobed gland in vertebrates. Produces the hormone thyroxine.

thyroxine Hormone produced by the thyroid gland; controls many metabolic processes.

calcitonin Hormone produced by the thyroid gland; lowers blood calcium and promotes bone formation. (Contrast with parathyroid hormone.)

(A) Cross section of a thyroid gland

(B) Production of T_3 and T_4 hormones by the thyroid gland

Figure 40.11 The Thyroid Gland Consists of Many Follicles (A) Cross section through a thyroid gland, showing numerous follicles bounded by epithelial cells. Calcitonin-secreting cells are located in the spaces between the follicles. **(B)** The epithelial cells of the follicle synthesize thyroglobulin and secrete it into the lumen of the follicle, where it is iodinated and stored until it is processed by the epithelial cells to generate T_3 and T_4 .

Thyroxine, a crucial signal in the regulation of cellular energy metabolism, begins as the glycoprotein thyroglobulin, which is synthesized by the follicle cells and packaged in secretory vesicles. The follicle cells actively take up iodide from the blood and move it into the lumen of the follicle (**Figure 40.11B**). Each thyroglobulin molecule contains about 100 tyrosine units. When the secretory vesicles release thyroglobulin into the lumen of the follicle, they also release an enzyme that catalyzes the iodination of the tyrosine units in the thyroglobulin. When the thyroid gland is stimulated to release thyroxine, the follicle cells take up thyroglobulin from the follicle by endocytosis. These bits of thyroglobulin are then cleaved to form smaller molecules consisting of only two tyrosine units, and these molecules leave the follicle cells and enter the blood. If these molecules are iodinated at the maximum of four sites on the tyrosine units, the hormone is tetraiodothyronine, or T_4 :

and if they are iodinated at only three sites, they are triiodothyronine, or T_3 :

The thyroid usually releases about ten times as much T_4 as T_3 . However, T_3 is a more active hormone than T_4 , so when you read about the effects of thyroxine, keep in mind that the actions discussed are primarily those of T_3 . The difference in the activities of T_3 and T_4 makes it possible to control the effects of thyroxine in different tissues. Within target cells, T_4 can be converted to T_3 by an enzyme called deiodinase. A different deiodinase can convert T_4 into an inactive hormone called reverse T_3 . Deiodinase can also inactivate T_3 by converting it into T_2 or T_1 . Thus each target cell can set a unique sensitivity to thyroid hormones using these enzymes to control the conversion of T_4 to T_3 or to reverse T_3 .

TSH AND TRH REGULATE THYROXINE PRODUCTION

The tropic hormone **thyroid-stimulating hormone (TSH)**, also known as **thyrotropin**, produced by the anterior pituitary, activates the thyroxine-producing follicle cells in the thyroid. Thyrotropin-releasing hormone (TRH), produced in the hypothalamus and transported to the anterior pituitary through the portal blood vessels, activates the TSH-producing pituitary cells. The hypothalamus uses environmental information, such as temperature or day length, to determine whether to increase or decrease its secretion of TRH. This sequence of steps is regulated by a negative feedback loop (see [Figure 40.7B](#)). Circulating thyroxine inhibits the response of pituitary cells to TRH, so less TSH is released when thyroxine levels are high, and more TSH is released when thyroxine levels are low. Circulating thyroxine also exerts negative feedback on the production and release of TRH by the hypothalamus.

thyroid-stimulating hormone (TSH) Hormone produced by the anterior pituitary that stimulates the thyroid gland to produce and release thyroxine. Also called thyrotropin.

TSH See thyroid-stimulating hormone.

thyrotropin Hormone produced by the anterior pituitary that stimulates the thyroid gland to produce and release thyroxine. Also called thyroid-stimulating hormone (TSH).

Because thyroxine is lipid-soluble, it enters cells readily and binds to receptors in the nucleus. When combined with thyroxine, these receptors (which are found in most cells of the body) stimulate the transcription of numerous genes whose products are transport proteins, structural proteins, and enzymes involved in metabolic pathways; thus thyroxine elevates the metabolic rates of most cells and tissues. Exposure to cold for several days leads to an increased release of thyroxine, an increased conversion of T_4 to T_3 , and therefore an increased basal metabolic rate (see [Key Concept 39.5](#)).

During development and growth, thyroxine promotes amino acid uptake and protein synthesis.

Insufficient thyroxine in a human fetus or growing child greatly retards physical and mental development, resulting in a condition known as cretinism.

GOITER

A **goiter** is an enlarged thyroid gland (**Figure 40.12**) that can be associated with either hyperthyroidism (excess production of thyroxine) or hypothyroidism (thyroxine deficiency). The negative feedback loop whereby thyroxine controls TSH release helps explain how two seemingly opposite conditions can result in the same symptom.

goiter Swelling in the neck resulting from an enlarged thyroid gland.

Figure 40.12 A Hypothyroid Goiter In this condition, dietary iodide deficiency leads to a lack of functional thyroxine, resulting in the oversynthesis of thyroglobulin and subsequent enlarged follicles.

- The most common cause of **hyperthyroid** goiter is Graves' disease, an autoimmune disease involving an antibody to the TSH receptor. This antibody binds to and activates the TSH receptors on the follicle cells, causing uncontrolled production and release of thyroxine. Blood levels of TSH are low due to negative feedback from high levels of thyroxine, but the thyroid remains maximally stimulated and grows bigger. People with hyperthyroidism have high metabolic rates, usually feel hot, and may develop a buildup of fat behind the eyeballs that causes their eyes to bulge.
- *Hypothyroid* goiter results when there is not enough circulating thyroxine to turn off TSH production. The most common cause is a deficiency of dietary iodide, without which the follicle cells cannot make thyroxine. Without sufficient thyroxine, TSH levels remain high and the

thyroid continues to produce large amounts of thyroglobulin. Because sufficient iodine is not available, however, the thyroglobulin is poorly iodinated. When it is broken down by the follicle cells, it produces little functional T₃ or T₄. TSH levels remain high and stimulate more and more synthesis of thyroglobulin, and the thyroid gets bigger. The symptoms of hypothyroidism are low metabolism, intolerance of cold, and general physical and mental sluggishness.

Goiter affects about 5 percent of the world's population. The addition of iodide to table salt has greatly reduced the incidence of hypothyroid goiter in industrialized nations, but the condition is still common in other parts of the world and is a leading cause of intellectual impairment.

Three hormones regulate blood calcium concentrations

The regulation of calcium concentration in the blood is crucial, and shifts in blood calcium concentration above or below a narrow range can cause serious problems. When blood calcium falls below this range, the nervous system becomes overly excited, resulting in muscle spasms and even seizures. When blood calcium rises above this range, the nervous system becomes depressed and muscles—including the heart—weaken. Regulation of blood calcium is difficult because only about 0.1 percent of the calcium in the body is located in the extracellular fluid. About 1 percent is in cells, and almost 99 percent is in the bones. Therefore the body must maintain a tiny pool of calcium in the blood at a precise concentration, and that tiny pool can be influenced greatly by relatively small shifts in the much larger pools of calcium in the cells and bones.

The body has multiple mechanisms for changing blood calcium levels, including:

Deposition or absorption of bone

Excretion or retention of calcium by the kidneys

Absorption of calcium from the digestive tract

These mechanisms are controlled by three hormones: calcitonin, parathyroid hormone, and calcitriol (synthesized from vitamin D).

Animation 40.3 **Hormonal Regulation of Calcium** www.Life11e.com/a40.3

CALCITONIN REDUCES BLOOD CALCIUM

Calcitonin is released by the thyroid and lowers the concentration of calcium in the blood, mainly by regulating bone turnover (**Figure 40.13**). Bone is continuously remodeled through a dynamic process that involves both resorption of old bone and synthesis of new bone, as we will discuss in **Key Concept 47.3**. Cells called osteoclasts break down bone and release calcium into the blood, and cells called osteoblasts take up calcium from the blood and deposit it in new bone. Calcitonin decreases the activity of osteoclasts and thereby favors removal of calcium from the blood and its deposition in bone by osteoblasts. The turnover of bone in adult humans is not very high, so calcitonin does not play a major role in calcium homeostasis in adults. It is probably more important in young individuals whose bones are actively growing.

calcitonin Hormone produced by the thyroid gland; lowers blood calcium and promotes bone formation. (Contrast with parathyroid hormone.)
--

Figure 40.13 Hormonal Regulation of Calcium Calcitonin, parathyroid hormone (PTH), and calcitriol (the active form of calciferol, or vitamin D) regulate Ca²⁺ levels in the blood.

PARATHYROID HORMONE INCREASES BLOOD CALCIUM

The **parathyroid glands** are four tiny structures embedded in the posterior surface of the thyroid gland (see [Figure 40.13](#)). Their single hormone product, **parathyroid hormone (PTH)**, also called parathormone, is the most important hormone in the regulation of blood calcium levels. Circulating calcium activates receptors in the cell membrane of the parathyroid cells. When these receptors are active, they inhibit the synthesis and release of PTH. A fall in blood calcium removes this inhibition and triggers the synthesis and release of PTH. PTH stimulates bone turnover by actions on both osteoclasts and osteoblasts. The end result of these actions of PTH is a net increase of calcium in the blood. PTH also maintains blood concentration of calcium by stimulating the kidneys to reabsorb it rather than excrete it in the urine.

parathyroid glands Four glands on the posterior surface of the thyroid gland that produce and release parathyroid hormone.

parathyroid hormone (PTH) A hormone secreted by the parathyroid glands that stimulates osteoclast activity and raises blood calcium levels. Also called parathormone. (Contrast with calcitonin.)

CALCITRIOL INCREASES BLOOD CALCIUM

It had long been known that fragile bones were common among people living at high latitudes, where winter days are short and the winter diet often lacks fish, dairy products, and fresh vegetables. Since the condition could be reversed by taking cod-liver oil, it was assumed that a vitamin deficiency was involved. That vitamin was named vitamin D, but when its chemical identity was established, this molecule turned out not to be a vitamin at all.

A vitamin is a substance that the body requires in small quantities but cannot synthesize for itself and must therefore obtain from food (or from supplements such as vitamin pills). However, vitamin D—now more accurately named calciferol—is synthesized naturally from cholesterol when skin cells receive ultraviolet light. Calciferol is not an active hormone, but through actions of the liver and kidneys it is converted into the active form called **calcitriol**, which circulates in the blood and acts on distant cells (and therefore is a hormone). The conversion of calciferol to calcitriol is activated by PTH. Calcitriol promotes the absorption of calcium from food in the gut. Thus the combined actions of PTH and calcitriol raise blood calcium levels.

calcitriol A hormone derived from vitamin D whose actions include stimulating the cells of the digestive tract to absorb calcium from ingested food.

PTH lowers blood phosphate levels

Bones are made of phosphate as well as calcium. When PTH stimulates the release of calcium from bone, it also releases phosphate. Normal blood concentrations of calcium and phosphate are just below the levels at which they precipitate out of solution as calcium phosphate salts. Even a small rise in concentrations may cause precipitation that leads to maladies such as kidney stones and calcium deposits in the arteries (hardening of the arteries). To reduce this risk, PTH acts on the kidneys to increase the elimination of phosphate via the urine.

Insulin and glucagon regulate blood glucose concentrations

Before the 1920s, the disease diabetes mellitus was fatal. Characterized by weakness, lethargy, and a dramatic loss of body mass, this condition was known to be connected somehow with the pancreas—a large gland located just below the stomach (see [Figure 40.5](#))—and with abnormal glucose metabolism. The exact links, however, were not clear.

Today we know there are two forms of diabetes mellitus. The form that was mostly seen prior to the 1920s usually occurred in young people and was called juvenile diabetes. We now call it type I diabetes, and it is caused by a lack of the protein hormone **insulin**. Glucose enters cells by diffusion, but cell membranes are not very permeable to glucose. Glucose transporter proteins in cell membranes facilitate the movement of glucose into cells, and the glucose transporters called GLUT4 that are most common in muscle and adipose tissue are controlled by insulin. When insulin binds to its receptor on the cell membrane, it causes these glucose transporters to move from cytoplasmic vesicles to the cell membrane, thus making the cell more permeable to glucose ([Figure 40.14](#)). When insulin is not present, these transporters are returned to the cytoplasmic pool through endocytosis.

insulin (in' su lin) [L. *insula*: island] A hormone synthesized in islet cells of the pancreas that promotes the conversion of glucose into the storage material, glycogen.

Figure 40.14 Glucose Transporters Are Controlled by Insulin Most tissues of the body depend on insulin to promote the uptake of glucose into cells. Glucose enters cells by diffusion, but that diffusion is facilitated by passive glucose transporters. When insulin binds to receptors on the cell surface, it stimulates the transfer of one type of glucose transporter (GLUT4) from intracellular sequestration to the cell membranes. When insulin levels fall, the glucose transporters are again sequestered intracellularly.

The other form of diabetes, which is seen in epidemic proportions in the United States today, is called adult onset or type II diabetes. Type II diabetes is associated with obesity, high carbohydrate consumption, and lack of exercise. It is caused either by low production of insulin or by insensitivity to insulin. More than 90 percent of diabetes cases seen in the United States today are type II diabetes, and the numbers are rising alarmingly. Statistics from the Centers for Disease Control and Prevention show that the number of new cases of type II diabetes reported in the United States in 1991 was less than 600,000 and had been fairly stable since 1980. Between 1991 and 2012, the annual number of new cases tripled. Diabetes is currently the seventh leading cause of death in the United States, and it is a common contributor to blindness, kidney failure, stroke, heart disease, and amputations resulting from ulcerations. This disease is largely preventable and even reversible with lifestyle changes.

In both type I and type II diabetes, glucose entry into cells is impaired, resulting in so much glucose accumulating in the blood that it starts to spill over into the urine. A high concentration of glucose in the blood increases urine output by two mechanisms. First, it causes water to move from cells into the blood by osmosis, and this increase in blood volume results in increased urine production. Second, the increased glucose in the tubules of the kidneys pulls more water into the urine by osmosis. Diabetic individuals thus lack metabolic fuel, and they can also become dehydrated. Because glucose uptake by muscle and adipose tissue is impaired in the absence of insulin, muscle cells must depend on fat and protein for fuel and adipose tissue cannot replenish its stores of triglycerides. If the condition is not treated, the body wastes away.

For centuries, the prospects for people suffering with type I diabetes were bleak. A change came almost overnight in 1921, when the physician Frederick Banting and a medical student, Charles Best, at the University of Toronto, discovered they could reduce the symptoms of diabetes by injecting an extract prepared from pancreatic tissue. The active component of this extract was found to be insulin, a small protein consisting of just 51 amino acids. In the United States today, insulin replacement therapy using manufactured insulin allows more than 1.5

million people with type I diabetes to lead almost normal lives.

Much evidence now shows that type II diabetes can be treated with a combination of dietary changes and weight loss, and **Figure 40.15** looks at the intriguing question of whether the hormone irisin (introduced in the opening of this chapter) can mediate the beneficial effects of exercise on glucose metabolism in type II diabetes patients.

experiment

Figure 40.15A Effects of Exercise on Glucose Metabolism

Original Paper: Zhang, Y. et al. 2014. Irisin stimulates browning of white adipocytes through mitogen-activated protein kinase p38 MAP kinase and ERK MAP kinase signaling. *Diabetes* 63; 514–525.

Exercise has been shown to have benefits for individuals with type II diabetes and for obese individuals. Imaging studies have revealed an inverse correlation between brown fat abundance and body mass—lean people have more brown fat and obese people have less. Given that irisin has been shown to have a “browning” effect on white fat, making it more metabolically active, might irisin mediate the beneficial effects of exercise on glucose metabolism and body mass?

HYPOTHESIS▶ Irisin can mediate exercise-induced improvements in glucose metabolism.

METHOD

1. For 2 weeks, treat mice with daily injections of irisin (experimental) to simulate effects of exercise. Treat control mice with injections of saline.
2. After 2 weeks, sacrifice mice and collect fat tissues to analyze for expression of genes for uncoupling protein (UCP1, an indication of irisin’s “browning” effect) and betatrophin (βt , a peptide that stimulates proliferation of insulin-secreting cells in the pancreas).
3. Determine the average expression for the two genes under control and experimental conditions. Determine the standard deviations. Do *t*-tests to determine if the treatment (irisin injections) had a significant effect on the expression of genes for UCP1 and for βt .

RESULTS

The table shows gene expression (in arbitrary units) in white adipose tissue (simulated data based on published means and SDs). The bar graph shows the mean expression levels of the two genes ± 1 SD.

CONCLUSIONS

1. The treatment with irisin resulted in a significant increase ($P < 0.001$) in expression of UCP1 in the white fat, demonstrating the known effect of irisin.
2. The treatment with irisin also resulted in a significant increase in the expression of βt ($P < 0.001$), which could stimulate insulin production in the pancreas.

		Relative gene expression of individual								Mean	SD
Gene	Treatment group	1	2	3	4	5	6	7	8		
UCP1	Control (1)	1.42	1.42	1.40	1.42	1.38	1.41	1.40	1.41	1.41	0.01
UCP1	Experimental (2)	23.46	21.68	28.2	26.36	25.77	22.99	28.72	26.13	25.41	2.50

work with the data

Figure 40.15B Effects of Exercise on Glucose Metabolism

Original Paper: Zhang et al. 2014.

Figure 40.17A showed that elevated irisin levels could stimulate pancreatic function in ways that could benefit individuals with type II diabetes. Betatrophin had been shown to stimulate proliferation of insulin-producing cells in the pancreas, increase release of insulin, and improve the ability of individuals to process glucose from dietary sources. The question then arose whether these health benefits associated with betatrophin could be stimulated by irisin treatment. Additional experiments were done to investigate this question. Researchers kept mice on a high-fat diet for 10 weeks and then treated half of the mice with daily injections of irisin for 2 weeks while the other half received daily saline injections (control). $N = 8$ for both groups. The table shows body mass before and after the two-week injection treatment, fasting insulin levels, and blood glucose levels. All values are means ± 1 standard deviation. Use an unpaired *t*-test to compare the body mass and fasting insulin of the two groups.

Group	Body mass (g) before	Body mass (g) after	Fasting insulin (ng/mL)	Blood glucose (mg/dL)
Control	40.1 $\pm$ 4.4	40.9 $\pm$ 4.8	4.3 $\pm$ 1.0	150 $\pm$ 5
Irisin treated	43.7 $\pm$ 2.7	40.2 $\pm$ 2.8	2.1 $\pm$ 0.5	130 $\pm$ 7

QUESTIONS

1. In the first experiment, why was it important to measure a known marker of brown fat function, namely UCP1, in the same experiment in which the expression of a new candidate gene, namely βt was being measured as a response to irisin treatment?
2. In the second experiment, why were the mice first placed on a high-fat diet?
3. Type II diabetes is frequently associated with obesity and is characterized by insulin resistance. As a result, insulin levels can be high while glucose metabolism is still impaired. What evidence was produced supporting the hypothesis that raised irisin levels could benefit obese individuals or individuals with type II diabetes?

A similar work with the data exercise may be assigned in LaunchPad.

ISLETS OF LANGERHANS

Insulin is produced in clusters of endocrine cells in the pancreas. These clusters are called **islets of Langerhans** after the German medical student who discovered them. They contain

three types of cells, each of which produces a specific hormone:

islets of Langerhans Clusters of hormone-producing cells in the pancreas.

- . Beta (β) cells produce and secrete insulin.
- . Alpha (α) cells produce and secrete [glucagon](#), a hormone that has effects mostly opposite from those of insulin.

glucagon Hormone produced by alpha cells of the pancreatic islets of Langerhans. Glucagon stimulates the liver to break down glycogen and release glucose into the circulation.

- . Delta (δ) cells produce the hormone [somatostatin](#).

somatostatin Peptide hormone made in the hypothalamus that inhibits the release of other hormones from the pituitary and intestine.

The rest of the pancreas is made up of exocrine tissue, which produces enzymes and other secretions that travel through ducts to the gut, where they participate in digestion.

After a meal, the concentration of glucose in the blood rises, stimulating the β cells of the islets to release insulin. Insulin causes target cells throughout the body to use circulating glucose as fuel and convert it into storage products such as glycogen and fat. When the gut is empty of food, blood glucose concentration falls and the islets stop releasing insulin. As a result, most cells shift to using glycogen and fat rather than glucose as fuel. If blood glucose concentration falls substantially below normal, the islet β cells release glucagon, which stimulates the liver to break down stored glycogen and release glucose into the blood. We will discuss these actions in greater detail in [Key Concept 50.4](#).

SOMATOSTATIN

Somatostatin is released from the δ cells of the pancreas in response to rapid increases of glucose and amino acids in the blood. This hormone has paracrine functions within the islets, where it inhibits the release of both insulin and glucagon. Outside the pancreas it acts as a hormone, slowing the digestive activities of the gut and extending the period during which nutrients are absorbed. Somatostatin is also produced in very small amounts by cells in the hypothalamus. Hypothalamic somatostatin, also called [growth hormone inhibiting hormone \(GHIH\)](#), is transported in the portal blood vessels to the anterior pituitary, where it inhibits the release of growth hormone and thyrotropin.

growth hormone inhibiting hormone (GHIH) Also called somatostatin, a peptide hormone produced in the hypothalamus that inhibits the activity of growth hormone secreting cells in the anterior pituitary.

The adrenal gland is two glands in one

An [adrenal gland](#) sits above each kidney, just below the middle of your back. Functionally and anatomically, each adrenal gland consists of a gland within a gland ([Figure 40.16](#)). The core, or [adrenal medulla](#), produces epinephrine and, to a lesser degree, norepinephrine. The medulla develops from nervous tissue and is under the control of the nervous system. Surrounding the medulla is the [adrenal cortex](#), which produces steroid hormones. The cortex is under hormonal

control, largely by a tropic hormone produced by cells in the anterior pituitary.

adrenal gland (a dree' nal) [L. *ad*: toward + *renes*: kidneys] An endocrine gland located near the kidneys of vertebrates, consisting of two parts, the adrenal cortex and adrenal medulla.

adrenal medulla Tissue that makes up the core of the adrenal gland and secretes epinephrine and norepinephrine.

adrenal cortex The outer region of the adrenal gland that produces and secretes steroid hormones.

Figure 40.16 The Adrenal Is Really Two Glands An adrenal gland, consisting of an outer cortex and an inner medulla, sits above each kidney. The medulla and the cortex produce different hormones.

THE ADRENAL CORTEX

The cells of the adrenal cortex use cholesterol to produce three classes of steroid hormones (see [Figure 40.2B](#)), collectively called **corticosteroids**:

corticosteroids Steroid hormones produced and released by the cortex of the adrenal gland.

- . *Mineralocorticoids* influence the salt and water balance of the extracellular fluid.
- . *Glucocorticoids* influence blood glucose concentrations as well as other aspects of fat, protein, and carbohydrate metabolism.

- . Sex steroids play roles in sexual development, sexual behavior, and anabolism (tissue building).

In adult humans, the adrenal cortex secretes only negligible amounts of sex steroids. The major producers of sex steroids are the gonads, as we saw in [Key Concept 40.3](#).

Aldosterone, the primary mineralocorticoid, stimulates the kidneys to conserve sodium and excrete potassium, as we will discuss in [Chapter 51](#). If the adrenal glands are removed from an animal, sodium must be added to its diet, or its sodium will be depleted and it will die.

aldosterone (al dohs' ter own) A steroid hormone produced in the adrenal cortex of mammals. Promotes secretion of potassium and reabsorption of sodium in the kidney.

The main glucocorticoid in humans is cortisol, which is **critical** for mediating the body's metabolic responses to stress. Within minutes of a stressful stimulus (one provoking fear or anger, for example), blood cortisol levels begin to rise. This response is much slower than the neurally mediated epinephrine and norepinephrine response to stress, but it lasts longer. Whereas epinephrine and norepinephrine cause sudden increases in blood pressure, cortisol causes a sustained increase in blood pressure. Cortisol stimulates tissues that are not critical for escaping the danger or threat to switch from using blood glucose for energy to using fats and proteins. This action preserves circulating glucose to fuel the actions of the nervous system and skeletal muscles necessary to meet the threat. Cortisol also raises blood pressure, to increase delivery of oxygen to the muscles to prepare them for flight or fight, and inhibits the immune system. Dealing with the immediate stressor is more important than feeling sick, having allergic reactions, or healing wounds. This explains why cortisol and drugs that mimic its action are useful for reducing inflammation and allergic responses. Cortisol decreases activity of the gut and reproductive systems—you can digest lunch and reproduce later if you escape the threat. You can see that actions of cortisol are adaptive in responding to acute stress, but they can cause problems if sustained over time, as sometimes occurs in modern society due to social, economic, and job-related stressors.

Cortisol release is controlled by **adrenocorticotrophic hormone (ACTH)** from the anterior pituitary. ACTH release is controlled in turn by **corticotropin-releasing hormone (CRH)** from the hypothalamus (see [Figure 40.7](#)). The action of ACTH on the adrenal cortex is to stimulate the synthesis of cortisol. Like other steroid hormones, cortisol is not stored in vesicles and therefore is available for immediate release. As cortisol or other steroid hormones diffuse into the blood, they combine with carrier proteins, and their release from these proteins can have a long time course, thus stretching out their actions. Also, many of their actions stimulate gene expression in target cells, which also takes time but has a long-lasting effect.

adrenocorticotrophic hormone (ACTH) See corticotropin.

corticotropin-releasing hormone (CRH) A hormone produced by the hypothalamus that controls the release of cortisol from the anterior pituitary.

Turning off the stress responses activated by cortisol is as important as turning them on. A study of stress in rats showed that old rats could turn on these stress responses as effectively as young rats, but they had lost the ability to turn them off as rapidly. As a result, they suffered from the well-known consequences of stress seen in humans: digestive system problems, cardiovascular problems, strokes, impaired immune system function, and increased susceptibility to cancers and other diseases. Acute stress responses are turned off by negative feedback from cortisol on both the ACTH-secreting cells of the anterior pituitary and the CRH-

secreting cells of the hypothalamus. With chronic or prolonged stress, these control mechanisms become insufficient and cortisol must exert negative feedback through another brain region, the hippocampus. Prolonged exposure to cortisol, however, causes trauma to and loss of hippocampal cells, resulting in the decreased ability to turn off the stress response.

Loss of adrenal cortical function results in Addison's disease, which is characterized by fatigue, muscle weakness, digestive problems, low blood sodium (hyponatremia), low blood pressure, and salt hunger. Without replacement hormone treatment, death is likely. An interesting symptom of Addison's disease is darkening of many skin areas that normally are not exposed to the sun—for instance, the lining of the cheeks. You can understand the cause of this symptom by thinking about the source of ACTH and the control of its secretion. In the hypothalamic-pituitary-endocrine gland axis (see [Figure 40.7](#)), an end hormone (in this case cortisol) frequently serves as a negative feedback signal to the pituitary and also the hypothalamus. If the hormones of the adrenal cortex are absent, the negative feedback is also gone, and the system will call for more ACTH. The production of ACTH by pituitary cells involves the expression of a polypeptide called proopiomelanocortin which is then cleaved to produce multiple peptide hormones. These include ACTH, MSH, endorphins, and enkephalins. The excess production of MSH is the cause of the skin darkening in Addison's disease.

THE ADRENAL MEDULLA

Stress causes the adrenal medulla to release epinephrine and norepinephrine that arouse the body to action. As we saw earlier in this chapter, epinephrine and norepinephrine increase heart rate and blood pressure and divert blood flow to active muscles and away from the gut and skin. Only about one-fifth as much norepinephrine is secreted from the adrenal medulla as epinephrine, but it has similar functions. Norepinephrine is also used by the nervous system as a neurotransmitter, and it is involved in controlling many physiological processes.

Epinephrine and norepinephrine are both water-soluble, and both bind to the same set of receptors on the surfaces of target cells. These [adrenergic receptors](#) are of two general types, α -adrenergic and β -adrenergic. The α -adrenergic receptors respond more strongly to norepinephrine than to epinephrine, whereas β -adrenergic receptors respond about equally to both epinephrine and norepinephrine. Because of this difference in receptor affinities, it is possible for drugs to blunt the flight-or-fight responses without disrupting physiological regulatory processes. Such drugs are called “beta blockers” because, by inhibiting β -adrenergic receptors, they can reduce the fight-or-flight response to epinephrine without disrupting the physiological regulatory functions of norepinephrine mediated through the α -adrenergic receptors. Beta blockers are commonly prescribed to reduce symptoms of anxiety such as dry mouth and elevated heart rate (palpitations).

adrenergic receptors G protein-coupled receptor proteins that bind to the hormones epinephrine and norepinephrine, triggering specific responses in the target cells.

Many chemicals may act as hormones

We have discussed the major mammalian endocrine glands and their hormones in this chapter, but many more hormones exist. As we discuss the organ systems of the body in the chapters that follow, we will frequently describe hormones that their tissues produce as well as hormones that control their functions.

The pineal gland has a daily cycle of melatonin release

Humans like most vertebrate species have a **pineal** gland located between the cerebral hemispheres. The pineal has a daily rhythm of production and secretion of the hormone [melatonin](#). The functions of the pineal and melatonin have to do with coordinating daily rhythms

of physiological functions and, in many species, seasonal changes such as reproduction timing, migration, and preparations for environmental stress such as cold weather.

melatonin A hormone released by the pineal gland. Involved in photoperiodicity and circadian rhythms.

40.4 recap

The major endocrine glands of mammals include the hypothalamus, pituitary gland, thyroid gland, parathyroid glands, pancreas, adrenal glands, gonads, and pineal gland. Each of these glands secretes and responds to hormones that play crucial roles in controlling physiology and development. Thyroxine is a lipid-soluble hormone that influences the expression of genes involved in regulating cell metabolism. Calcitonin and parathyroid hormone (PTH) regulate blood calcium levels, mainly by regulating the remodeling of bone. Blood glucose levels are controlled by insulin when blood glucose levels rise and largely by the lack of insulin when blood glucose levels fall. Glucagon is released in the event of serious hypoglycemia, and it stimulates breakdown of glycogen to raise blood glucose levels. The adrenal cortex produces steroid hormones, the most important of which is cortisol, which is involved in stress responses. The adrenal medulla produces epinephrine and norepinephrine.

learning outcomes

You should be able to:

- Explain the effects of disruptive changes in normal thyroxine levels on humans.
 - Describe calcitriol and its effects on calcium in the blood.
 - Describe how insulin and glucagon regulate blood sugar levels.
 - Apply concepts about hormonal control of stress to explain why prolonged stress can have negative effects on the body.
-
1. Describe how both hypothyroidism and hyperthyroidism can result in goiter.
 2. How does vitamin D contribute to raising blood calcium levels, and why is it not a vitamin?
 3. How does insulin control the rate of glucose uptake by cells?
 4. Explain how chronic stress can lead to stress-related diseases.

In what ways could irisin mediate the health benefits of exercise?

Q/A The initial discovery of irisin and its functions revealed that it induces brown fat-like changes in white fat, including expression of the gene that codes for uncoupling protein (UCP1), which enables brown fat cells to metabolize lipids without producing ATP. As a result, metabolism in the brown fat cells is not inhibited by the buildup of ATP or the lack of ADP, and the brown fat can simply metabolize

excess energy and generate heat.

Exercise does more than promote weight loss and toned muscles. It also improves cognition and glucose metabolism. Improving glucose metabolism can help reverse the changes associated with type II diabetes—elevated blood glucose, elevated blood insulin, loss of sensitivity of the pancreas to glucose, and loss of sensitivity of body tissues to insulin. Investigating Life: How Could Irisin Mediate the Benefits of Exercise on Cognition? and [Figure 40.15](#) present experiments showing that irisin is a mediator of benefits of exercise on cognition and glucose metabolism. It seems likely that irisin is a major integrating factor in a large suite of healthful benefits of exercise.

Future directions

The experiments explored in Investigating Life: How Could Irisin Mediate the Benefits of Exercise on Cognition? and [Figure 40.15](#) suggest the interesting possibility that irisin could be developed as a therapeutic that might be useful in treating the national epidemic of obesity and type II diabetes. It might also prove to be beneficial in cognitive declines due to conditions such as stroke and Alzheimer's disease. Before such treatments can be developed, however, research is needed on such questions as: Are there potential negative side effects of abnormal elevations of irisin? Is there the potential for abuse of irisin, similar to what has been seen with other growthpromoting agents such as growth hormone and testosterone? It would seem that the safest way to benefit from the actions of irisin would be to use the natural approach of regular exercise to promote its normal production and release.

▶ 40.1 Hormones Circulate Around the Body and Affect Target Cells

- Endocrine cells secrete chemical signals that induce responses in other cells that have receptors for those molecules. In some cases endocrine cells are aggregated into [endocrine glands](#).

endocrine gland (en' doh krin) [Gk. *endo*: within + *krinein*: to separate] An aggregation of secretory cells that secretes hormones into the blood. The endocrine system consists of all endocrine cells and endocrine glands in the body that produce and release hormones. (Contrast with exocrine gland.)

- Hormones** are endocrine signals that are secreted from a cell, circulate in the blood, and bind to target cells distant from the secreting cell. [Review Figure 40.1](#)
- Hormones** fall into three general categories: [protein](#) and [peptide hormones, steroid hormones](#), and [amine hormones](#). Peptide and protein hormones and some amine hormones are water-soluble; steroid hormones and some amine hormones are lipid-soluble. [Review Figure 40.2](#)

hormone (hore' mone) [Gk. *hormon*: to excite, stimulate] A chemical signal produced in minute amounts at one site in a multicellular organism and transported to another site where it acts on target cells.

protein (pro' teen) [Gk. *protos*: first] Long-chain polymer of amino acids with twenty different common side chains. Occurs with its polymer chain extended in fibrous proteins, or coiled into a compact macromolecule in enzymes and other globular proteins. The component amino acids are encoded in the triplets of messenger RNA, and proteins are the products of genes.

peptide hormones Hormone molecules made up of chains of 2 to 50 amino acids (upper size arbitrary); encoded by genes and produced by translation.

amine hormones Small hormone molecules synthesized from single amino acids (e.g., thyroxine and epinephrine).

- Receptors for water-soluble hormones are located on the cell surface. Receptors for most lipid-soluble hormones are inside the cell.
- The same hormone can cause different responses in different target cells. [Review Figure 40.3](#)
- The chemical structures of hormones are highly conserved. Through evolution, however, hormones acquire different functions in different animal groups. [Review Figure 40.4](#)
- In humans, the major endocrine glands are distributed around the body. [Review Figure 40.5, Activity 40.1](#)

▶ 40.2 The Endocrine System and Nervous System Work Together

- The **pituitary gland** is the interface between the nervous and endocrine systems. The **anterior pituitary** develops from embryonic mouth tissue; the **posterior pituitary**

develops from the developing brain. **Review Figure 40.6, Focus: Key Figure 40.7**

- The posterior pituitary secretes two **neurohormones: antidiuretic hormone (ADH)** and **oxytocin**. The anterior pituitary secretes **tropic hormones** (thyrotropin, adrenocorticotropin, luteinizing hormone, and follicle-stimulating hormone) as well as **growth hormone**, prolactin, **endorphins**, **enkephalins**, and **melanocyte stimulating hormone**.

neurohormone A chemical signal produced and released by neurons that subsequently acts as a hormone.

oxytocin A hormone released by the posterior pituitary that promotes social bonding.

tropic hormones Hormones produced by the anterior pituitary that control the secretion of hormones by other endocrine glands.

growth An increase in the size of the body and its organs by cell division and cell expansion.

endorphins Molecules in the mammalian brain that act as neurotransmitters in pathways that control pain.

enkephalins Molecules in the mammalian brain that act as neurotransmitters in pathways that control pain.

- The anterior pituitary is controlled by neurohormones produced by cells in the hypothalamus and transported through **portal blood** vessels to the anterior pituitary. **See Animation 40.1**
- Hormone release is controlled in part by negative feedback loops.
- The hormone irisin may mediate effects of exercise on the brain. **Review Investigating Life: How Could Irisin Mediate the Benefits of Exercise on Cognition?**

▶ 40.3 Hormones Play Important Roles in Development

- Pioneering experiments in illustrating hormonal action showed that two hormones, PTTH and ecdysone, control molting in arthropods. A third hormone, **juvenile hormone**, prevents maturation. **Review Figure 40.8, Animation 40.2**

juvenile hormone In insects, a hormone maintaining larval growth and preventing maturation or pupation.

- Sex hormones (**androgens** in males, **estrogens** and **progesterone** in females) control sexual development, secondary sexual characteristics, and reproductive functions. **Review Figures 40.9, 40.10**

androgen (an' dro jen) Any of the several male sex steroids (most notably testosterone).

estrogen Any of several steroid sex hormones; produced chiefly by the ovaries in mammals.

progesterone [L. *pro*: favoring + *gestare*: to bear] A female sex hormone that maintains pregnancy.

▶ 40.4 Hormones Regulate Metabolism and the Internal Environment

- The **thyroid gland** is controlled by **thyroid-stimulating hormone (TSH)**, also called **thyrotropin**) and secretes **thyroxine**, which controls cell metabolism. **Review Figure 40.11**

thyroid gland [Gk. *thyreos*: door-shaped] A two-lobed gland in vertebrates. Produces the hormone thyroxine.

thyroid-stimulating hormone (TSH) Hormone produced by the anterior pituitary that stimulates the thyroid gland to produce and release thyroxine. Also called thyrotropin.

thyrotropin Hormone produced by the anterior pituitary that stimulates the thyroid gland to produce and release thyroxine. Also called thyroid-stimulating hormone (TSH).

thyroxine Hormone produced by the thyroid gland; controls many metabolic processes.

- The level of calcium in the blood is regulated by three hormones. **Calcitonin** from the thyroid lowers blood calcium by promoting bone deposition. **Parathyroid hormone (PTH)** raises blood calcium by promoting bone turnover and decreasing calcium excretion. **Calcitriol** promotes calcium absorption from the digestive tract. **Review Figure 40.13, Animation 40.3**

calcitonin Hormone produced by the thyroid gland; lowers blood calcium and promotes bone formation. (Contrast with parathyroid hormone.)

parathyroid hormone (PTH) A hormone secreted by the parathyroid glands that stimulates osteoclast activity and raises blood calcium levels. Also called parathormone. (Contrast with calcitonin.)

calcitriol A hormone derived from vitamin D whose actions include stimulating the cells of the digestive tract to absorb calcium from ingested food.

- The pancreas secretes three hormones. **Insulin** stimulates glucose uptake by cells and lowers blood glucose. **Glucagon** raises blood glucose, and **somatostatin** slows the rate of nutrient processing. **Review Figure 40.14**

insulin (in' su lin) [L. *insula*: island] A hormone synthesized in islet cells of the pancreas that promotes the conversion of glucose into the storage material, glycogen.

glucagon Hormone produced by alpha cells of the pancreatic islets of Langerhans. Glucagon stimulates the liver to break down glycogen and release glucose into the circulation.

somatostatin Peptide hormone made in the hypothalamus that inhibits the release of other hormones from the pituitary and intestine.

- The **adrenal gland** has two portions, one within the other. The inner portion, the **adrenal medulla**, releases epinephrine and norepinephrine in response to stress. The outer portion, the **adrenal cortex**, produces three classes of **corticosteroids**: glucocorticoids, mineralocorticoids, and small amounts of sex steroids. **Review Figure 40.16**

adrenal gland (a dree' nal) [L. *ad*: toward + *renes*: kidneys] An endocrine gland located near the kidneys of vertebrates, consisting of two parts, the adrenal cortex and adrenal medulla.

adrenal medulla Tissue that makes up the core of the adrenal gland and secretes epinephrine and norepinephrine.

adrenal cortex The outer region of the adrenal gland that produces and secretes steroid hormones.

corticosteroids Steroid hormones produced and released by the cortex of the adrenal gland.

- **Aldosterone** is a mineralocorticoid that stimulates the kidneys to conserve sodium and excrete potassium. **Cortisol** is a glucocorticoid that is released in response to stressful stimuli but acts more slowly than the hormones of the adrenal medulla.

aldosterone (al dohs' ter own) A steroid hormone produced in the adrenal cortex of mammals. Promotes secretion of potassium and reabsorption of sodium in the kidney.

cortisol A corticosteroid that mediates stress responses.

- The **pineal gland** releases **melatonin**, a hormone involved in controlling biological rhythms.

pineal gland Gland located between the cerebral hemispheres that secretes melatonin.

melatonin A hormone released by the pineal gland. Involved in photoperiodicity and circadian rhythms.

See Activity 40.2 for a concept review of this chapter.

Review

- 0.1 Hormones affect target cells that have appropriate receptors.
- 0.1 Different target cells can respond to the same hormone in different ways depending on the signal transduction pathway stimulated.

Original Paper: Corbett, M. C. and A. B. Richards. 1994. Intraocular adrenaline maintains mydriasis during cataract surgery. *British Journal of Ophthalmology* 78: 95-98.

The opening in the iris forms the pupil of the eye. The iris is composed of two arrangements of smooth muscle fibers. Constrictor muscles surrounding the pupil are arranged in concentric circles, like tree rings. Peripheral to the constrictor fibers are the dilator fibers, which are arranged like the spokes on a bicycle wheel. When the constrictor muscles contract, the pupil becomes very small, and when the dilators contract, the pupil becomes large.

Aging and exposure to UV light can cause the lens of the eye to become cloudy and nontransparent—a condition known as a cataract. To restore sight, a surgeon must remove the cataract through the pupil. To facilitate this surgery it is important to dilate the pupil as much as possible and to keep it dilated as long as possible. Pupillary dilation is facilitated by the sympathetic nervous system and the adrenal medulla releasing epinephrine (adrenaline) and norepinephrine.

Could epinephrine be used to maintain pupil dilation during cataract surgeries? To find out, researchers studied the effects of adding epinephrine to the irrigation fluid injected into the eye during cataract-removal surgery. Twenty-seven patients received irrigation fluid containing epinephrine at a concentration of 1:1,000,000. Forty-three patients received irrigation fluid without epinephrine. The table below shows the percentage of patients with pupil diameter less than 5 mm at various stages during cataract surgery.

Stage of surgery	Without epinephrine (%)	With epinephrine (%)
Start	0	0
After lens removal	16	0

After soft tissue removal	21	7
10 min after surgery	9	4
20 min after surgery	21	4
30 min after surgery	21	9

Questions

1. In this experiment, which part of the iris is being affected by the epinephrine injection? Explain your answer based on the experimental results of the two surgeries.
2. Both parts of the iris are composed of smooth muscle tissue. Propose a hypothesis to explain why the epinephrine produced the observed experimental effect.
3. Epinephrine is a hormone released during the normal fight-or-flight response in mammals. Name some of the other tissue and organ changes that occur during this response, and discuss why they respond so differently to epinephrine than the smooth muscle in the iris does.
4. The drug atropine, a known acetylcholine receptor inhibitor, is also used to dilate the pupil. It affects the pupillary constrictor muscle. What can you conclude about how atropine causes pupillary dilation? What are the implications of this for how the autonomic nervous system controls pupil diameter?

Vaccines and Immunity

Five tiny vials in deep freezers, three in Bethesda, Maryland, one in Atlanta, Georgia, and one in Siberia, are all that is left of the smallpox virus. Smallpox killed more than 300 million people in the twentieth century, but the disease made its last appearance in 1978, thanks to vaccination. A vaccine is usually an inactive form of a pathogen or toxin that provokes the immune system to produce antibodies: specific proteins directed against the target. The immune system destroys whatever is bound to the antibodies.

The eradication of smallpox was a spectacular international accomplishment. So why hasn't vaccination for other potentially lethal diseases such as the flu (influenza) been widely accepted by the public? More than one-third of Americans refuse flu shots, and a significant number of parents refuse vaccination for their children.

Unfortunately, those who refuse vaccination may harm people other than themselves. A vaccination program can control or eradicate a disease only if a high percentage (typically above 80 percent) of people are vaccinated, thus disrupting the chain of infection from person to person. A very high level of vaccination results in "herd immunity," a state in which even those who cannot be vaccinated or who have weak immune systems are protected from infection. This protection is lost if the vaccination rate falls below the level needed for herd immunity. Those who are old or sick, and infants whose immune systems have not yet fully developed, are most at risk.

The best way to develop herd immunity in a population is compulsory vaccination. In many countries, vaccination is a prerequisite for school enrollment and military enlistment and is required during epidemics. For example, during the periodic smallpox epidemics during the twentieth century in the United States, doctors accompanied by police would go into neighborhoods where the disease raged, vaccinating all those who were uninfected and removing infected people to quarantine. You can imagine the reaction of parents whose children were taken away, often to die. Henning Jacobson was arrested when he refused vaccination during a smallpox epidemic. He took his case to the U.S. Supreme Court, which ruled in 1905 that while personal freedom is important, each state is entitled to protect its citizens. This provided a legal framework for compulsory vaccination that continues to this day. But opposition and court challenges continue.

What are the mechanisms and implications of long-lasting immunity?

41.1 Animals Use Innate and Adaptive Mechanisms for Defense

Animals have several ways of defending themselves against **pathogens**—harmful organisms and viruses that can cause disease. These defense systems are based on the distinction between *self*—the animal's own molecules—and *nonself*, or foreign, molecules.

pathogen (path' o jen) [Gk. *pathos*: suffering + *genesis*: source] An organism that causes disease.

focus your learning

The two general types of defense mechanisms are innate defenses and adaptive defenses.

Many animal groups have Toll-like receptors (TLRs) that participate in innate defense responses.

All white blood cells originate from multipotent stem cells in the bone marrow.

In mammals, the major immune system proteins include antibodies, MHC proteins, T cell receptors, and cytokines.

The defensive response involves three phases:

- . *Recognition phase.* The organism must be able to discriminate between self and nonself.
- . *Activation phase.* The recognition event leads to a mobilization of cells and molecules to fight the invader.
- . *Effector phase.* The mobilized cells and molecules destroy the invader.

There are two general types of defense mechanisms:

- . **Innate defenses**, or *nonspecific defenses*, are *inherited mechanisms that provide the first line of defense against pathogens*. Innate defenses typically act very rapidly and include barriers such as the skin, molecules that are toxic to invaders, and phagocytic cells that ingest invaders. (Recall from [Key Concept 6.5](#) that phagocytosis is a form of endocytosis, in which a cell engulfs a large particle or another cell.) The innate immune system recognizes broad classes of organisms and molecules, such as viruses, bacteria, fungi, protists, worms, and various toxins.

innate defenses In animals, one of two general types of defenses against pathogens. Nonspecific and present in most animals. (Contrast with adaptive defenses.)

- . **Adaptive defenses** are *aimed at specific pathogens and are activated by the innate immune system*. For example, the adaptive immune system can make an antibody protein that will recognize, bind to, and aid in the destruction of a specific pathogen, if that specific pathogen ever enters the body. Adaptive defenses are typically slower to develop than the innate

defenses and longer-lasting.

adaptive defenses One of the two general types of defenses against pathogens. Involves antibody proteins and other proteins that recognize, bind to, and aid in the destruction of specific viruses and bacteria. Present only in vertebrate animals. (Contrast with innate defenses.)

Immunity occurs when an organism has sufficient defenses to successfully avoid the effects of biological invasion by a pathogen.

immunity [L. *immunis*: exempt from] In animals, the ability to avoid disease when invaded by a pathogen by deploying various defense mechanisms.

Innate defenses evolved before adaptive defenses

All animals have innate defenses against their enemies. For example, the arthropod *Tachypleus tridentatus*—the Japanese horseshoe crab—first appeared in the fossil record about 400 million years ago. It relies only on innate defenses. These defenses include barriers, defensive cells, and defensive molecules.

Barriers include physical, chemical, and biological mechanisms for resisting infections. The horseshoe crab has the hard exoskeleton that is characteristic of arthropods. This shell acts to protect the crab from invasion by pathogens.

Cells involved in innate defenses include phagocytes that bind to microbial pathogens, ingest them by endocytosis, and destroy them by hydrolysis. Amebocytes in the blood of the horseshoe crab fulfill this defensive role.

Molecules that are toxic to invading pathogens are important in innate defense. The horseshoe crab has a wide array of such molecules that are released from cells in its blood. These molecules include peptides that disrupt the bacterial cell membrane, rendering it permeable; and peptides that bind to bacterial surfaces and cross-link them.

Studies of innate immunity, along with genome sequencing, have revealed that the recognition and activation phases of innate immunity evolved very early in animals. For example, animals as diverse as humans and fruit flies share a class of receptors, called **Toll-like receptors (TLRs)**, that participate in innate defense responses. These receptors recognize nonself molecules called *** pathogen-associated molecular patterns (PAMPs)**. In vertebrates, each Toll—like receptor recognizes and binds to a specific molecule that is found in a broad class of pathogens, such as a component of the bacterial cell wall. Binding triggers a signal transduction pathway that ends with the expression of genes for anti—pathogen molecules (**Figure 41.1**). This pathway exists in some form in many animal groups, including humans.

Toll-like receptors (TLRs) Membrane proteins of macrophages and dendritic cells with extracellular domains that recognize molecules from microbial pathogens.

Figure 41.1 Cell Signaling and Defense Binding of a pathogenic molecule or fragment to the Toll—like receptor initiates a signal transduction pathway that results in the transcription of genes whose products are involved in adaptive and innate defenses.

Mammals have both innate and adaptive defenses

Mammals have both kinds of defense mechanisms, and these mechanisms are the focus of this chapter. In mammals, the innate and adaptive mechanisms operate together as a coordinated defense system. [Table 41.1](#) gives an overview of these defenses during the course of an infection. Innate immunity is the body’s first line of defense because the adaptive defenses often require days or even weeks to become effective.

table 41.1 Innate and Adaptive Immune Responses to an Infection

Response time	System	Mechanisms
Early (0–4 hr)	Innate, nonspecific (first line)	Barrier (skin and lining of organs) Dryness, low pH Mucus Lysozyme, defensins
Middle (> 4–96 hr)	Innate, nonspecific (second line)	Inflammation Phagocytosis Natural killer cells Complement system Interferons
Late (> 96 hr)	Adaptive,	Humoral immunity

Blood and lymph tissues play important roles in defense

The components of the mammalian defense system are dispersed throughout the body and interact with almost all of its other tissues and organs. The lymphoid tissues, which include the thymus, bone marrow, spleen, and lymph nodes, are essential parts of the defense system (**Figure 41.2**). The blood and lymph are complex systems with nondefensive functions that will be discussed in [Chapter 49](#). They each have central roles in defense as well.

Figure 41.2 The Human Lymphatic System A network of ducts and vessels collects lymph from body tissues and carries it toward the heart, where it mixes with blood to be pumped back to the tissues. Other lymphoid tissues, including the thymus, spleen, and bone marrow, are also essential to the body's defense system.

The blood and lymph both consist of liquids in which cells are suspended:

Blood plasma is a yellowish solution containing ions, small molecule solutes, and soluble proteins. Suspended in the plasma are red blood cells, white blood cells, and platelets (cell fragments essential to blood clotting). Whereas red blood cells are normally confined to the closed circulatory system (the heart, arteries, capillaries, and veins), white blood cells and platelets are also found in the lymph.

blood plasma (plaz' muh) The liquid portion of blood, in which blood cells and other particulates are suspended.

Lymph is a fluid that is derived from the blood (but lacking red blood cells) and other tissues and accumulates in intercellular spaces throughout the body. From these spaces, the lymph moves slowly into the vessels of the lymphatic system. Tiny lymph capillaries conduct this fluid to larger ducts that eventually join together, forming two large vessels, the thoracic duct and right lymphatic duct, which join a major vein (the left subclavian vein) near the heart. By this system of vessels, the lymph is eventually returned to the blood and the circulatory system.

lymph [L. *lympa*: liquid] A fluid derived from blood and other tissues that accumulates in intercellular spaces throughout the body and is returned to the blood by the lymphatic system.

At many sites along the lymph vessels are small, roundish structures called **lymph nodes**, which contain a type of white blood cell called a **lymphocyte**. As lymph passes through a lymph node, the lymphocytes encounter foreign cells and molecules that have entered the body, and if they are recognized as nonself, an immune response is initiated.

lymph node A specialized structure in the vessels of the lymphatic system. Lymph nodes contain lymphocytes, which encounter and respond to foreign cells and molecules in the lymph as it passes through the vessels.

lymphocyte One of the two major classes of white blood cells; includes T cells, B cells, and other cell types important in the immune system.

White blood cells play many defensive roles

One milliliter of human blood typically contains about 5 *billion* red blood cells and 7 *million* of the larger **white blood cells** (also called leukocytes). All of these cells originate from multipotent stem cells (constantly dividing undifferentiated cells that can form several different cell types; see [Key Concept 19.1](#)) in the bone marrow. There are two major families of white blood cells: lymphocytes and phagocytes (**Figure 41.3**). Lymphocytes include the B cells and T cells; they are smaller than other white blood cells and are not phagocytic. **Phagocytes** include most of the other cells shown in **Figure 41.3**, and as their name suggests, they are phagocytic. Each kind of white blood cell has specialized functions. Some phagocytes are also referred to collectively as granulocytes because they contain numerous granules (vesicles containing defensive molecules). Defensive proteins and signals play fundamental roles in the interactions and functioning of these cells.

white blood cells Cells in the blood plasma that play defensive roles in the immune system. Also called leukocytes.

phagocyte [Gk. *phagein*: to eat + *kystos*: sac] One of two major classes of white blood cells;

one of the nonspecific defenses of animals; ingests invading microorganisms by phagocytosis.

Type of cell		Function
	Basophils (I, A)	Release histamine
	Eosinophils (A)	Kill antibody—coated parasites
	Neutrophils (I)	Stimulate inflammation; engulf and digest microorganisms
	Mast cells (I)	Release histamine when damaged
	Monocytes (I, A)	Develop into macrophages and dendritic cells
	Macrophages (I, A)	Engulf and digest microorganisms; activate T cells
	Dendritic cells (A)	Present antigens to T cells
	Natural killer cells (I)	Attack and lyse virus—infected or cancerous body cells
		Differentiate to form antibody—producing cells and memory cells

	B lymphocytes (A)	
	T lymphocytes (A)	Kill virus—infected cells or cancer cells; regulate activities of other white blood cells

Figure 41.3 White Blood Cells White blood cells have key roles in both innate (I) and adaptive (A) immunity. The lymphocytes are the B cells and T cells; the other cell types are phagocytes.

 Activity 41.2 **Cells of the Immune System** www.Life11e.com/ac41.2

Immune system proteins bind pathogens or signal other cells

The cells that defend mammalian bodies work together, interacting with one another and with the cells of invading pathogens. These cell—cell interactions are accomplished by a variety of key proteins, including receptors, other cell surface proteins, and signaling molecules. Four of the major players are listed here, and will be discussed in more detail later in the chapter.

- **Antibodies** are proteins that bind specifically to certain substances identified by the immune system as nonself. The specific molecules that bind to antibodies are called **antigens**. Antibodies are produced by B cells.

antibody One of the myriad proteins produced by the immune system that specifically binds to a foreign substance in blood or other tissue fluids and initiates its removal from the body.

antigen (an' ti jun) Any substance that stimulates the production of an antibody or antibodies in the body of a vertebrate.

- **Major histocompatibility complex (MHC)** proteins are used to display antigens on the surfaces of self cells, so that the antigens can be detected by the T cells of the immune system. MHC proteins also function as important self—identifying labels.

major histocompatibility complex (MHC) A complex of linked genes, with multiple alleles, that control a number of cell surface antigens that identify self and can lead to graft rejection.

- **T cell receptors** are integral membrane proteins on the surfaces of T cells. They recognize and bind to antigens presented by the MHC proteins on the surfaces of other cells.

T cell receptor A protein on the surface of a T cell that recognizes the antigenic determinant for which the cell is specific.

- **Cytokines** are soluble signaling proteins released by many cell types. They bind to cell surface receptors and alter the behavior of their target cells.

41.1 recap

All animals have innate defenses against pathogens, and vertebrates have innate and adaptive defenses. Both kinds of mechanisms are based on the ability to differentiate self from nonself. Innate defenses target a broad range of molecules and organisms, whereas adaptive defenses target specific pathogens. Both innate and adaptive defenses involve specialized white blood cells.

learning outcomes

You should be able to:

- Compare various types of defense mechanisms.
- Describe the role of the Toll-like receptor (TLR) pathway in innate immunity.
- Infer what types of immune-related molecules and genes a particular animal would have.

1. Describe three characteristics of innate immunity and adaptive immunity that distinguish them from each other.
2. Some people have a rare genetic disease that results in defective signaling in the TLR pathway. What would be the phenotype of such individuals?
3. If you compared the genomes of an insect and a human with regard to the presence of genes involved in immunity, what might you find?

The outcome of an infectious disease — the life or death of the host—often depends on the success of both rapid, innate responses and long—lasting, adaptive responses to invading pathogens. We will turn now to the innate defenses that protect vertebrates from disease.

***connect the concepts** The recognition of PAMPs is widespread in immunity and is therefore an evolutionarily ancient mechanism. Plants have an immune response to invading pathogens that also involves PAMPs. See [Key Concept 38.1](#).

41.2 Innate Defenses Are Nonspecific

Innate defenses are general protection mechanisms that attempt to stop pathogens from invading the body or to quickly eliminate those that do manage to invade. They are genetically programmed (innate) and “ready to go,” in contrast to adaptive responses, which take time to develop after a pathogen or toxin has been recognized as nonself.

focus your learning

Innate immunity is applied to any potential harmful invader.

Physical barriers, such as skin, are the first line of innate defense.

Inflammation involves recruitment of cells and defensive molecules to an area damaged by a pathogen or other injury.

Innate immunity is sometimes described as nonspecific immunity because it is applied indiscriminately to any potentially harmful invader. There are two lines of innate defense (**Figure 41.4**). The first line of innate defense is encountered by a potential pathogen as soon as it lands on the surface of an animal. Consider a pathogenic bacterium that lands on human skin. The challenges faced by the bacterium just to reach its target are formidable:

Figure 41.4 Innate Immunity Physical barriers, cells, and proteins (complement and interferons) provide nonspecific defenses against invading pathogens.

Media Clip 41.1 **The Chase Is On: Phagocyte versus Bacteria**

www.Life11e.com/mc41.1

The *physical barrier of the skin*: Bacteria rarely penetrate intact skin, which has about 30 cell layers; by the same token, broken skin increases the risk of infection.

The *saltiness and dryness of skin*: This environment may not be hospitable to the growth of the bacterium.

The *presence of normal flora*: Bacteria and fungi that normally live and sometimes reproduce in great numbers on our body surfaces without causing disease will compete with pathogens for space and nutrients.

If a pathogen lands inside the nose or another internal organ, it faces other innate defenses:

Mucus is a slippery secretion produced by mucous membranes found at the inner surfaces of the nose (as well as the digestive, respiratory, and urogenital systems). Mucus traps microorganisms so they can be removed by the beating of cilia (see [Figure 5.17](#)), which continuously move the mucus and its trapped debris away.

mucus A viscous substance secreted by mucous membranes (e.g., mucosal epithelium). A barrier defense against pathogens in innate immunity in animals and a protective coating in many animal organ systems.

Lysozyme is an enzyme made by cells of the mucous membranes that attacks the cell walls of many bacteria, causing them to lyse (burst open).

lysozyme (lie' so zyme) An enzyme in saliva, tears, and nasal secretions that hydrolyzes bacterial cell walls.

Defensins, also made by mucous membranes, are peptides of 18–45 amino acids that contain hydrophobic domains. They are toxic to a wide range of pathogens, including bacteria, microbial eukaryotes, and enveloped viruses. Defensins insert themselves into the cell membranes of these organisms and make the membranes permeable, thus killing the invaders. Defensins are also produced in phagocytes, where they kill pathogens ingested by phagocytosis. Plants also produce ***defensins** in response to pathogen exposure.

defensin A type of protein made by phagocytes that kills bacteria and enveloped viruses by insertion into their plasma membranes.

Harsh conditions in an animal's internal environment can also kill pathogens. For example, gastric juice in the stomach is a deadly environment for many bacteria because of the hydrochloric acid and proteases that are secreted into it.

Specialized proteins and cells participate in innate immunity

Several proteins are produced by the body either before an infection occurs or in response to invasion by pathogens. Two important groups are the complement and interferon proteins.

COMPLEMENT PROTEINS

Vertebrate blood contains more than 20 different proteins that make up the antimicrobial **complement system**. This system can be activated by various mechanisms, including both innate and adaptive defense responses. The proteins act in a characteristic sequence, or cascade, with each protein activating the next:

complement system A group of eleven proteins that play a role in some reactions of the immune system. The complement proteins are not immunoglobulins.

- . First, the proteins attach to specific components on the surface of a microbe or to an antibody that has already bound to the microbe's surface. In either case, binding helps phagocytes recognize and destroy the microbe.
- . Then, complement proteins activate the inflammatory response (see [Figure 41.5](#)) and attract phagocytes to the site of infection.
- . Finally, complement proteins lyse invading cells (such as bacteria).

INTERFERONS

When a cell is infected by a pathogen, it produces small amounts of signaling proteins called [interferons](#) that increase the resistance of neighboring cells to infection. Interferons are a class of cytokines and have been found in many vertebrates. Various molecules, including double—strand (viral) RNA, induce the production of interferons. Thus interferons are particularly important as a defense against viruses. Interferons bind to receptors on the cell membranes of uninfected cells, stimulating a signaling pathway that inhibits viral reproduction if the cells are subsequently infected. In addition, interferons stimulate the cells to hydrolyze bacterial or viral proteins to peptides, an initial step in adaptive immunity (see [Key Concept 41.3](#)).

interferons Glycoproteins produced by virus-infected animal cells; interferons increase the resistance of neighboring cells to the virus.

PHAGOCYTES

Some phagocytes travel freely in the circulatory and lymphatic systems; others can move out of blood vessels and adhere to certain tissues. Pathogenic cells, viruses, or fragments of these invaders are recognized by phagocytes, which then ingest them by phagocytosis.

Defensins, nitric oxide, and reactive oxygen intermediates inside these phagocytes then kill the pathogens.

NATURAL KILLER CELLS

One class of lymphocytes, known as **natural killer cells**, can distinguish virus-infected cells and some tumor cells from their normal counterparts and initiate apoptosis (programmed cell death) of these target cells. In addition to this innate defense action, natural killer cells interact with the adaptive defense mechanisms by lysing antibody—labeled target cells.

DENDRITIC CELLS

These phagocytes occur in tissues exposed to the environment, such as skin and the linings of the digestive and respiratory tracts, as well as in blood. They act as messengers between the innate and adaptive immune systems. They can endocytose microbes, viruses, and even remnants of the virus-infected host cells. Once inside a dendritic cell, these particles are digested to fragments, and the dendritic cell “presents” an antigenic fragment on its surface, along with class **II MHC** proteins (see [Key Concept 41.5](#)). In addition, the dendritic cell secretes signals that activate cells of the adaptive immune system.

Inflammation is a coordinated innate response to infection or injury

When mammalian tissue is damaged because of infection or injury, the body responds with inflammation. This response can happen almost anywhere in the body, internally as well as on the surface. Inflammation is an important phenomenon: it isolates the damaged area to stop the spread of the damage; it recruits cells and molecules to the damaged location to kill the invader; and it promotes healing. The first responders to tissue damage are [mast cells](#), which adhere to the skin and the linings of organs and release numerous chemical signals, including:

mast cells Cells, typically found in connective tissue, that release histamine in response to tissue damage.

[Tumor necrosis factor](#), a cytokine protein that kills target cells and activates immune cells.

tumor necrosis factor A family of cytokines (growth factors) that causes cell death and is involved in inflammation.

[Prostaglandins](#), fatty acid derivatives involved in various responses, including the widening of blood vessels. Prostaglandins interact with nerve endings and are partly responsible for the pain caused by inflammation.

prostaglandin Any one of a group of specialized lipids with hormone-like functions. It is not clear that they act at any considerable distance from the site of their production.

[Histamine](#), an amino acid derivative that leads to the important process of dilation of blood vessels, as well as itchy, watery eyes and rashes seen with some types of allergic reactions.

histamine (hiss' tah meen) A substance released by damaged tissue, or by mast cells in response to allergens. Histamine increases vascular permeability, leading to edema (swelling).

The redness and heat of inflammation result from the dilation and leakiness of blood vessels in the infected or injured area ([Figure 41.5](#)). Phagocytes enter the inflamed area, where they engulf the invaders and dead tissue cells. Phagocytes are responsible for most of the healing associated with inflammation. They produce several cytokines, which (among other functions)

can signal the brain to produce a fever. This rise in body temperature accelerates lymphocyte production and phagocytosis, thereby speeding the immune response. In some cases, pathogens are temperature-sensitive and their growth is inhibited. The pain of inflammation results from increased pressure due to swelling, the action of leaked enzymes on nerve endings, and the action of prostaglandins, which increase the sensitivity of the nerve endings to pain.

Figure 41.5 Interactions of Cells and Chemical Signals Result in Inflammation

Histamine and other signals are released from mast cells to initiate the inflammatory response. The chemical signals associated with inflammation attract phagocytes, which digest the pathogens and damaged cells.

Q: Antihistamines are a class of drugs widely used to treat people with inflammation. How do you think they work?

Activity 41.3 Inflammatory Response www.Life11e.com/ac41.3

Following inflammation, pus may accumulate. Pus is a mixture of leaked fluid and dead cells: bacteria, neutrophils (the most abundant white blood cells—see [Figure 41.3](#)), and damaged body cells. Pus is a normal result of inflammation and is gradually consumed and further digested by macrophages.

41.2 recap

Innate immunity is the first line of defense against pathogens. Innate immunity includes physical barriers such as the skin, and cellular responses involving the recognition of self and nonself molecules. Recognition of nonself molecules by white blood cells leads to coordinated responses such as the production of defensive proteins and inflammation.

learning outcomes

You should be able to:

- Summarize the roles of physical barriers, chemical defenses, and cellular defenses in innate immunity.
 - Explain how the innate defense system defends against a pathogen.
 - List the steps in the inflammatory response.
-

1. A pathogenic bacterium lands on your skin. Outline the innate defenses that come into play.
2. Your immune system does not mount an innate defense response to a speck of dust that lands on your skin, but it may mount an innate response to a bacterium. Why?
3. When a splinter of wood permeates the skin, the skin swells up. Outline the events by which this occurs.

Often the innate immune system, with its nonspecific defenses, is adequate to prevent or fight off a pathogenic infection. But in many cases this system works together with adaptive immunity, which detects and responds to specific pathogens. We will now turn to the development and functioning of adaptive immunity.

***connect the concepts** [Key Concept 38.1](#) describes constitutive and cellular responses to pathogens in plants. Among these are the pathogenesis—related (PR) proteins, which are similar to defensins produced by animals. These small peptides bind to fungal membranes and are toxic to a wide range of fungal targets, but they are not toxic to plant or animal cells. Other PR proteins may serve as alarm signals to plant cells that have not yet been attacked.

41.3 Adaptive Defenses Are Specific

More than a century ago, experiments showed that guinea pigs that were infected with bacteria that cause diphtheria produced a chemical in their blood that can protect other guinea pigs from infection. This observation led to the concept of adaptive immunity and to the understanding that factors promoting immunity are found in blood.

focus your learning

The humoral and cellular immune responses work simultaneously and cooperatively.

Memory cells, the key to immunological memory, retain the capacity to divide to produce effector and more memory cells.

Vaccinations initiate a primary immune response, generating memory cells without causing illness.

In this section we outline the main features of the adaptive immune system. We will consider the two major types of adaptive responses: the humoral immune response, which produces antibodies; and the cellular immune response, which destroys infected cells.

What are the key features of adaptive immunity?

Four important features of the adaptive immune system are:

- . Specificity
- . The ability to distinguish self from nonself
- . The ability to respond to an enormous diversity of nonself molecules
- . Immunological memory

SPECIFICITY

Lymphocytes (B and T cells) are crucial components of adaptive immunity. T cell receptors and the antibodies produced by B cells recognize and bind to specific nonself substances (antigens), and this interaction initiates an adaptive immune response. The specific sites on antigens that the immune system recognizes are called [antigenic determinants](#), or [epitopes](#):

antigenic determinant The specific region of an antigen that is recognized and bound by a specific antibody. Also called an epitope.

epitope See antigenic determinant.

An antigenic determinant is a specific portion of a large molecule, such as a certain sequence of amino acids that may be present in a protein. Antigens are usually proteins or polysaccharides, and there can be multiple antigens on a single invading bacterium. A single antigenic molecule can have multiple, different antigenic determinants. The host animal responds to the presence of an antigen with highly specific defenses involving T cell receptors and antibodies. These receptors and soluble proteins bind to the antigenic determinants. Each T cell and each antibody is specific for a single antigenic determinant. For the remainder of the chapter, we will refer to antigenic determinants simply as “antigens.”

DISTINGUISHING SELF FROM NONSELF

You have seen how the innate immune system distinguishes between self and nonself molecules. The adaptive immune system has another set of mechanisms for distinguishing self from nonself. The human body contains tens of thousands of different molecules, each with a specific three-dimensional structure capable of generating immune responses. Thus every cell in the body has a tremendous number of antigens. A crucial requirement of an individual's adaptive immune system is that it recognize the body's own antigens and not attack them.

DIVERSITY

Challenges to the immune system are numerous. Pathogens take many forms: viruses, bacteria, protists, fungi, and multicellular parasites. Furthermore, each pathogenic species usually exists as many subtly different genetic strains, and each strain possesses multiple surface features. Estimates vary, but a reasonable guess is that humans can respond specifically to 10 million different antigens. Upon recognizing an antigen, the adaptive immune system responds by activating lymphocytes of the appropriate specificity.

IMMUNOLOGICAL MEMORY

After the adaptive immune system responds to a particular type of pathogen once, the adaptive immune system “remembers” that pathogen and can usually respond more rapidly and powerfully to the same threat in the future. This [immunological memory](#) usually saves us from repeats of childhood diseases such as chicken pox.

immunological memory The capacity to more rapidly and massively respond to a second exposure to an antigen than occurred on first exposure.

All four of these features of adaptive immune defense characterize both the humoral immune response and the cellular immune response.

Macrophages and dendritic cells play a key role in activating the adaptive immune system

As you have seen, one way to eliminate pathogens with the innate immune system is phagocytosis. After ingestion of a pathogenic organism or infected host cell, phagocytic cells display fragments of the pathogen on their cell surfaces. These fragments function as antigens, and [antigen presentation](#) is one way that components of the innate immune system communicate with the adaptive immune system. Macrophages and dendritic cells play a key role in activating the adaptive immune system. After engulfing pathogens or infected host cells, these

cells migrate to lymph nodes, where they present antigen to immature (previously unexposed) T cells. In addition, the antigen-presenting cells secrete cytokines and other signals that stimulate the activation and differentiation of the T cells.

antigen presentation In cellular immunity, a process in which a cell ingests and digests an antigen, and then exposes fragments of that antigen to the outside of the cell, bound to proteins in the cell's cell membrane.

Two types of adaptive immune responses interact

The adaptive immune system mounts two types of responses against invaders: the humoral immune response and the cellular immune response. These two responses work simultaneously and cooperatively, sharing many mechanisms. We will use the example of a viral infection in an overview of these two types of responses (**Focus: Key Figure 41.6**). These responses also occur when bacteria or other pathogens infect and grow inside host cells.

focus: key figure

Figure 41.6 The Adaptive Immune System Humoral immunity involves the production of antibodies by B cells. Cellular immunity involves the activation of cytotoxic T cells that bind to cells expressing the antigen. For further details, see [Figure 41.13](#).

Q: In AIDS, a virus infects T_H cells and kills them. What would be the effects on adaptive immunity?

B cells that make antibodies are the workhorses of the [humoral immune response](#), and

cytotoxic T (T_C) cells are the workhorses of the cellular immune response. There are three phases in both types of adaptive immune response:

B cell A type of lymphocyte involved in the humoral immune response of vertebrates. Upon recognizing an antigenic determinant, a B cell develops into a plasma cell, which secretes an antibody. (Contrast with T cell.)

humoral immune response The response of the immune system mediated by B cells that produces circulating antibodies active against extracellular bacterial and viral infections. (Contrast with cellular immune response.)

cytotoxic T (T_C) cells Cells of the cellular immune system that recognize and directly eliminate virus-infected cells. (Contrast with T-helper cells.)

- **Recognition phase:** In both cellular and humoral immunity, recognition occurs when an antigen is inserted into the cell membrane of an antigen-presenting cell, with the unique antigen structure protruding from the cell membrane. In addition to dendritic cells and macrophages, developing B cells can also perform phagocytosis and function as antigen—presenting cells. A virus—infected host cell can be engulfed by an antigen-presenting cell, or the free viral particles may be engulfed. The antigen on the surface of the antigen-presenting cell is recognized by a **T-helper (T_H) cell** bearing a T cell receptor protein that is specific for the antigen. In both humoral and cellular immunity, binding initiates the activation phase.
- **Activation phase:** When the T_H cell recognizes an antigen on an antigen—presenting cell, it propagates and releases cytokines that stimulate B cells and T_C cells bearing receptors to the same antigen to divide. The results are a clone of B cells that function in humoral immunity and a clone of T_C cells that function in cellular immunity.
- **Effector phase:** In the humoral immune response, cells of the B clone produce antibodies that bind to viral particles and/or virus—infected cells. The bound antibodies attract phagocytes and complement proteins that engulf and destroy the virus and the virus—infected cells. In cellular immunity, cells of the T_C clone bind to virus—infected cells and destroy them.

 Animation 41.1 Pregnancy Test www.Life11e.com/a41.1

Adaptive immunity develops as a result of clonal selection

Before the humoral and cellular immune responses can take place, the body needs to generate a vast diversity of lymphocytes that have the ability to bind different antigens. How does this tremendous diversity arise? As we will discuss in [Key Concept 41.4](#), this diversity is generated primarily by DNA changes—chromosomal rearrangements and other mutations—that occur just after the B and T cells are formed in the bone marrow. Millions of different B cells develop, each of which can produce only one kind of antibody. Similarly, there are millions of different T cells, each with one specific kind of T cell receptor. Thus the adaptive immune system is “predeveloped”—*all of the machinery available to respond to an immense diversity of antigens is already there, even before the antigens are ever encountered.*

As we have described, when a pathogen enters the vertebrate body it stimulates the innate immune system. In addition to triggering its own defensive responses, the innate immune system triggers adaptive defensive responses via specific antigens that are presented on the surfaces of antigen—presenting cells, particularly dendritic cells. This triggers the proliferation of lymphocytes (B and T cells) that are specific for those particular antigens. How does this proliferation occur? The answer lies in the process of **clonal selection**: *antigen binding “selects” a particular B or T cell for proliferation.* When an antigen fits the surface receptor on a B or T cell

and binds to it, that cell is activated. It divides to form a clone of cells (a genetically identical group derived from a single cell), all of which recognize and react to the same antigen. This process is illustrated for B cells in **Figure 41.7**. Binding and activation select a particular lymphocyte, while proliferation generates the clone, hence the term “clonal selection.”

clonal selection Mechanism by which exposure to antigen results in the activation of selected T- or B-cell clones, resulting in an immune response.

Figure 41.7 Clonal Selection in B Cells The binding of an antigen to a specific receptor on the surface of a B cell stimulates that cell to divide, producing a clone of genetically identical cells to fight that invader. Plasma cells have extensive

endoplasmic reticulum for synthesizing antibodies.

Q: You may never have been exposed to Ebola virus. Do you have cells that make antibodies against this virus? Explain.

Clonal deletion helps the immune system distinguish self from nonself

Normally the body is tolerant of its own molecules. One way that the immune system does this is through the process of **clonal deletion**. This occurs during the early differentiation of T and B cells, when these cells encounter self antigens. Any immature B or T cell that shows the potential to mount an immune response against self antigens undergoes apoptosis within a short time.

clonal deletion Inactivation or destruction of lymphocyte clones that would produce immune reactions against the animal's own body.

Immunological memory results in a secondary immune response

The first time a vertebrate animal is exposed to a particular antigen there is a time lag (usually several days) before the B cell—produced antibody molecules and T cells specific to that antigen slowly increase. But for years afterward—sometimes for life—the immune system “remembers” that particular antigen, allowing the body to mount a faster response the next time it encounters the antigen. How does this happen?

The answer lies in the fact that activated lymphocytes divide and differentiate to produce **two types** of daughter cells: effector cells and memory cells.

- **Effector cells** carry out the attack on the antigen. Effector B cells, called **plasma cells**, secrete antibodies. Effector T cells release cytokines and other molecules that initiate reactions that destroy nonself or altered cells. Effector cells live only a few days.

effector cells In cellular immunity, B cells and T cells that attack an antigen, either by secreting antibodies that bind to the antigen or by releasing molecules that destroy any cell bearing the antigen.

plasma cell An antibody-secreting cell that develops from a B cell; the effector cell of the humoral immune system.

- **Memory cells** (see [Figure 41.7](#)) are long-lived cells that retain the ability to start dividing on short notice to produce more effector and more memory cells. Memory B and T cells may survive in the body for decades, rarely dividing.

memory cells Long-lived lymphocytes produced after exposure to antigen. They persist in the body and are able to mount a rapid response to subsequent exposures to the antigen.

Effector cells and memory cells can respond to an antigen in two different ways:

- When the body first encounters a particular antigen, a **primary immune response** is activated, in which the previously unexposed lymphocytes that recognize that antigen proliferate to produce clones of effector and memory cells.

primary immune response The first response of the immune system to an antigen, involving recognition by lymphocytes and the production of effector cells and memory cells. (Contrast with

secondary immune response.)

- After a primary immune response to a particular antigen, subsequent encounters with the same antigen will trigger a much more rapid and powerful **secondary immune response**. The memory cells that bind with that antigen proliferate, launching a huge army of plasma cells and effector T cells.

secondary immune response A rapid and intense response to a second or subsequent exposure to an antigen, initiated by memory cells. (Contrast with primary immune response.)

Vaccines are an application of immunological memory

Thanks to immunological memory, exposure to many diseases (including childhood diseases such as chicken pox) provides a natural immunity to those diseases. Furthermore, it is possible to provide artificial immunity against many life-threatening diseases by **vaccination**: the introduction of antigen into the body in a form that does not cause disease.

vaccination Injection of virus or bacteria or their proteins into the body, to induce immunity. The injected material is usually attenuated (weakened) before injection and is called a vaccine.

Vaccination initiates a primary immune response, generating memory cells without making the person ill. Later, if a pathogen carrying the same antigen attacks, specific memory cells already exist. They recognize the antigen and quickly overwhelm the invaders with a massive production of lymphocytes and antibodies.

Because of mutation, an antigenic determinant on a pathogen can change over time. If the change is significant in terms of three-dimensional structure, a vaccine directed against an antigen from a pathogen may become ineffective. You are familiar with this with regard to influenza. More often than not, the annual flu season features a genetic strain of the flu virus that is not sufficiently related to the previous season's vaccine; so a new vaccine, with new B cell clones, must be made. A remarkable recent finding is that memory cells can last a long time and help in a response to new, related antigens. People who were exposed to a particular strain of flu retain antibody-making memory cells against that strain for decades and develop a rapid immune response to a new, genetically different strain that appears years later. In the case of

flu, the memory cells are making antibodies that bind to not just the first strain of flu they responded to, but to later ones as well. Characterizing these antibodies provides a clue to developing a vaccine that is broadly effective and obviates the need to develop new ones (**Investigating Life: What Are the Mechanisms and Implications of Long-Lasting Immunity?**).

As you saw in the opening story, vaccination has completely or almost completely wiped out some deadly diseases in industrialized countries.

▶ investigatinglife What Are the Mechanisms and Implications of Long—Lasting Immunity?

experiment

Original Paper: Miller, M. et al. 2013. Neutralizing antibodies against previously encountered influenza virus strains increase over time: A longitudinal analysis. *Science Translational Medicine* 5: 1–9 (August 14 issue).

The Framingham Heart Study was begun in 1948 with the objective of finding out the causes of heart disease and stroke. About 5,000 people ages 30–62 and living in the town Framingham, Massachusetts, have been subjected every 2 years to extensive medical exams in an attempt to relate lifestyle factors to heart disease. Subsequent generations have been added to the study ever since. Not only has this study led to major findings about the causes of heart disease, but it has provided a wealth of data on other medical conditions as well. Peter Palese of the Icahn School of Medicine at Mount Sinai Hospital in New York City measured antibodies in blood to flu virus strains from 40 people in the Framingham study, born between 1917 and 1952. They had been exposed to major flu outbreaks in 1957, 1968, and 1977, as well as to the typical flu that comes up every year. Blood samples were examined between 1987 and 2008 to see if these people still had antibodies against the three major flu outbreak strains, and whether these antibody amounts increased over time as people fought off the new, less virulent strains that arise every year.

HYPOTHESIS ▶ Exposure to new strains of flu stimulates antibody production against strains to which an individual was exposed previously.

CONCLUSION ▶ People exposed to flu virus develop long-lasting memory cells that make antibodies that have broad specificity to other flu strains.

investigatinglife work with the data follows on next page.

METHOD

- 1 Obtain blood samples from people born between 1917 and 1952 who had been exposed to Asian flu (1957), Hong Kong flu (1968), and Russian flu (1977).

RESULTS

QUESTIONS▶

1. Blood samples were taken from 1987 to 2008, and the people's reactivity against various flu strains was tested. The results for antibodies against the Russian flu strain of 1977 in numerous individuals are shown in **Figure A**. Note that these people were exposed to many flu strains after 1977. The data shown are typical for the way specific immune reactions are measured. The titer is presented as a reciprocal. For example, a titer of 2 means that undiluted serum sample gave an antibody reaction (titer 1), and so did a dilution of 1 part serum and 1 part water (dilution of 1/2, reciprocal = 2). If the sample was diluted to a titer of 4 (1 part serum, 3 parts water), there was no reaction because the concentration of antibody was too low. The higher the titer number, the more the blood serum could be diluted to still react with the antigen; that is, a higher titer number means that there were more antibodies in the original serum sample. What can you conclude about the titer of anti-Russian flu strain over the years 1987–2008?
2. The flu virus mutates rapidly. In contrast, another virus to which people are exposed, cytomegalovirus (CMV), does not mutate rapidly. Antibody titer against CMV were measured, and the data are shown in **Figure B**. What can you conclude from these data? Compare the antibody response to CMV over time with that against the Russian flu virus strain and comment.
3. A protein on the surface of the flu virus called hemagglutinin (HA) is exposed to the immune system because of its prominent location (**Figure C**). When the flu virus genes mutate, the "head" of the protein tends to accumulate more changes than the stalk. Thus the amino acid sequences of stalk regions of various flu strains are similar. The investigators measured antibodies to the stalk region that were either broadly reactive to various flu strains, or not broadly reactive. The results are shown in the table. What can you conclude about the broadly reactive antibodies? How does this provide a guide for the development of a broadly based flu vaccine?

Figure C

Figure A

Figure B

Type of antibodies to stalk region	Titer
Broadly reactive	4,080
Not broadly reactive	1,024

A similar **work with the data** exercise may be assigned in **LaunchPad**.

41.3 recap

The adaptive immune system reacts against nonself molecules called antigens. The system generates amazing diversity in both antibodies (produced by B cells) and in T cell receptors. In the primary immune response, B cells and T cells that recognize a particular antigen proliferate by clonal selection. Immunological memory prepares the body for a much stronger secondary immune response.

learning outcomes

You should be able to:

- Distinguish between the recognition, activation, and effector phases in adaptive immunity.
- Make and explain inferences regarding rates of infection in the context of immunological memory.
- Summarize how vaccines provide long—lasting immunity to pathogens.

1. A fellow passenger sneezes on the train and the common cold virus enters your nose. Outline how your body responds, noting the kinds and stages of the adaptive immune response.
2. In 2009 the H1N1 strain of influenza spread around the world. People who had been alive at the time of the 1918 epidemic had low rates of infection. Explain this in terms of immunological memory.
3. How do vaccines make use of immunological memory?

The general features of the adaptive system are that it is pre-made to respond specifically to virtually any antigen, and it involves an initial primary response to the antigen and a more powerful secondary response when the same antigen is encountered in the future. As we noted, the adaptive system has a humoral response with B cells making antibodies and a cellular response with T cells expressing specific receptors. We now turn to these two types of adaptive response, beginning with the humoral system.

41.4 The Humoral Adaptive Response Involves Antibodies

Every day in the human body, billions of B cells survive the test of clonal deletion and are released from the bone marrow into the circulatory system. B cells are the basis for the humoral immune response.

focus your learning

Antibody proteins are immunoglobulins with four polypeptide chains—two identical light chains and two identical heavy chains, each with constant and variable regions.

IgG is the most common of the five classes of immunoglobulins.

DNA rearrangements and other mutations generate the diversity of immunoglobulins.

A B cell begins as an unexposed B cell with a receptor protein on its cell surface that is specific for a particular antigen. The cell is activated by antigen binding to this receptor, and after stimulation by a T_H cell it gives rise to a clone of plasma cells that make antibodies as well as a smaller number of memory cells (see [Figure 41.7](#)). The stimulation occurs after the B cell presents antigen to a T_H cell with a receptor that can recognize the antigen. The T_H cell then secretes cytokins that stimulate the B cell to divide.

Activated plasma cells (effector B cells) can synthesize and secrete large amounts of antibody proteins—up to 2,000 molecules per second! *All the plasma cells arising from a given B cell produce antibodies that are specific for the antigen that originally bound to the parent B cell.* Thus antibody specificity is maintained as B cells proliferate.

Animation 41.2 Humoral Immune Response www.Life11e.com/a41.2

Antibody protein structure reflects function

Antibodies belong to a class of proteins called [immunoglobulins](#). There are several types of immunoglobulins, but all contain a tetramer consisting of four polypeptide chains: two “heavy chains” and two “light chains” ([Figure 41.8](#)). In each immunoglobulin molecule, the two light chains are identical, and the two heavy chains are identical. Disulfide bonds hold the chains together, characteristically in a Y-like shape.

immunoglobulins A class of proteins containing a tetramer consisting of four polypeptide chains—two identical light chains and two identical heavy chains—held together by disulfide bonds; active as receptors and effectors in the immune system.

(A) General structure of an immunoglobulin

(B) Space-filling model of an immunoglobulin

Figure 41.8 The Structure of an Immunoglobulin Four polypeptide chains (two light, two heavy) make up an immunoglobulin molecule. Both diagrammatic **(A)** and space-filling **(B)** representations of immunoglobulin are shown here.

Each of the four polypeptide chains has a constant region and a variable region (designated C and V in [Figure 41.8A](#)):

The amino acid sequences of the [constant regions](#) are similar among the immunoglobulins. They determine the destination and function—the class—of each immunoglobulin.

constant region The portion of an immunoglobulin molecule whose amino acid composition determines its class and does not vary among immunoglobulins in that class. (Contrast with variable region.)

The amino acid sequences of the [variable regions](#) are different for each specific immunoglobulin. Their three-dimensional antigen-binding sites are determined by their secondary structures and are responsible for antibody specificity.

variable region The portion of an immunoglobulin molecule or T cell receptor that includes the antigen-binding site and is responsible for its specificity. (Contrast with constant region.)

Antigen—antibody binding is noncovalent. The attractive forces involved in holding antigen and antibody together include hydrogen bonding, ionic attractions, hydrophobic interactions, and van der Waals forces (see [Key Concept 2.2](#)). These attractive forces are generated from particular amino acids at the binding site on both molecules. So for an antibody protein, the sequence of amino acids at the binding site is crucial to its specificity. Generating antibody diversity is thus a molecular genetics challenge, as we will soon discuss.

The two antigen—binding sites on each immunoglobulin molecule are identical, making the antibody bivalent (*bi*, “two,” + *valent*, “binding”), meaning the molecule can bind two antigen molecules at once. Bivalency, in addition to the presence of multiple epitopes on the surfaces of many antigens (including large proteins, viruses, and bacteria, as you saw in the case of the influenza virus explored in Investigating Life: What Are the Mechanisms and Implications of Long—Lasting Immunity?), permits antibodies to form large complexes with the antigens. These complexes are easy targets for ingestion and breakdown by phagocytes.

There are five classes of immunoglobulins

While the variable regions are responsible for the specificity of an immunoglobulin, the constant regions of the heavy chain determine the class of the immunoglobulin. The five immunoglobulin classes are described in [Table 41.2](#). The most abundant class is IgG; these soluble antibody proteins make up about 80 percent of the total immunoglobulin content of the bloodstream. They are made in greatest quantity during a secondary immune response. IgG molecules defend the body in several ways. For example, after some IgG molecules bind to antigens, they become attached by their heavy chains to macrophages. This attachment permits the macrophages to destroy the antigens by phagocytosis.

table 41.2 Antibody Classes				
Class	General structure	Location	Function	
IgG	Monomer 	Free in blood plasma; about 80 percent of circulating antibodies	Most abundant antibody in primary and secondary immune responses; crosses placenta and provides passive immunization to fetus	
IgM	Pentamer 	Surface of B cell; free in blood plasma	Antigen receptor on B cell membrane; first class of antibodies released by B cells during primary response	

IgD	Monomer		Surface of B cell	Cell surface receptor of mature B cell; important in B cell activation
IgA	Dimer		Saliva, tears, milk, and other body secretions	Protects mucosal surfaces; prevents attachment of pathogens to epithelial cells
IgE	Monomer		Secreted by plasma cells in skin and tissues lining gastrointestinal and respiratory tracts	Binds to mast cells and basophils to sensitize them to subsequent binding of antigen, which triggers release of histamine that contributes to inflammation and some allergic responses

Immunoglobulin diversity results from DNA rearrangements and other mutations

Each mature B cell makes antibodies targeted to only one single antigen. And there are millions of possible antigens to which a human can be exposed. How can the genome encode enough different antibodies to protect the body against all the possible pathogens? Although there are millions of possible amino acid sequences in immunoglobulins, there are not millions of different immunoglobulin genes. It turns out that instead of a single gene encoding each complete immunoglobulin, the genome of the differentiating B cell has multiple different coding regions for each domain of the protein, and diversity is generated by putting together different combinations of these regions. Shuffling of this genetic deck generates the enormous immunological diversity that characterizes each individual mammal.

Each gene encoding an immunoglobulin chain is in reality a “supergene” assembled by means of genetic recombination from several clusters of smaller genes scattered along part of a chromosome (**Figure 41.9**). Every cell in the body has hundreds of immu—noglobulin genes located in separate clusters that are potentially capable of participating in the synthesis of both the variable and constant regions of immunoglobulin chains. In most body cells and tissues, these genes remain intact and separated from one another. But during B cell development, these genes are cut out, rearranged, and joined together in DNA recombination events. One

gene from each cluster is chosen randomly for joining, and the others are deleted. In the case of one multigene set, the **J** genes, some of the extra sequences are removed by RNA splicing (**Figure 41.10**).

Figure 41.9 Supergene Mouse immunoglobulin heavy chains have four domains, each of which is coded for by one of several possible genes selected from a cluster of similar genes. The immunoglobulin protein has one domain from each cluster.

Figure 41.10 Heavy—Chain Gene Recombination and RNA Splicing Two types of rearrangement in the heavy—chain gene clusters are required for antibody formation. **(A)** Prior to transcription, DNA is rearranged to join one each of the **V**, **D**, and **J** genes into a variable region supergene. **(B)** After transcription, RNA splicing joins the **VDJ** region to the constant region.

In this manner, a unique immunoglobulin supergene is assembled from randomly selected “parts.” Each B cell precursor assembles two supergenes, one for a specific heavy chain and the other, assembled independently, for a specific light chain. This remarkable example of irreversible cell differentiation generates an enormous diversity of immunoglobulins from the same genome. It is a major exception to the generalization that all somatic cells derived from the fertilized egg have identical DNA.

[Figure 41.9](#) illustrates the gene families that encode the constant and variable regions of the heavy chain in mice. Multiple genes encode each of the three parts of the variable region: 100 V, 30 D, and 6 J genes. Each B cell randomly selects one gene from each of these clusters to make the final coding sequence (**VDJ**) of the heavy—chain variable region. So the number of different heavy chains that can be made through this random recombination process is quite large:

$$100V \times 30 D \times 6 J = 18,000 \text{ possible combinations}$$

Now consider that the light chains are similarly constructed, with a similar amount of diversity made possible by random recombination. If we assume that the degree of potential light—chain diversity is the same as that for heavy—chain diversity, the number of possible combinations of light— and heavy—chain variable regions is:

$$18,000 \text{ different light chains} \times 18,000 \text{ different heavy chains} = 324 \text{ million possibilities}$$

~~18,000 different light chains × 18,000 different heavy chains = 324 million possibilities~~

Other mechanisms generate even more diversity:

When the DNA sequences that encode the V, D, and J regions are rearranged so that they are next to one another, the recombination event is not precise, and errors occur at the junctions. This imprecise recombination can create ***frame-shift mutations**, generating new codons at the junctions, with resulting amino acid changes.

After the DNA sequences are cut and before they are rejoined, the enzyme terminal transferase often adds some nucleotides to the free ends of the DNA pieces. These additional bases create insertion mutations.

There is a relatively high spontaneous mutation rate in immunoglobulin genes. Once again, this process creates many new alleles and adds to antibody diversity.

When we include these possibilities with the millions of combinations that can be made by random DNA rearrangements, it is not surprising that the immune system can mount a response to almost any natural or artificial substance.

Once the DNA rearrangements are completed, each supergene is transcribed and then translated to produce an immunoglobulin light chain or heavy chain. These chains combine to form an active immunoglobulin protein.

 Animation 41.3 A B Cell Builds an Antibody www.Life11e.com/a41.3

The constant region is involved in immunoglobulin class switching

[Table 41.2](#) describes the different classes of immunoglobulins and their functions. Generally, a B cell makes only one class at a time. But **class switching** can occur, in which a B cell changes the immunoglobulin class it synthesizes. For example, a B cell making IgM can switch to making IgG.

class switching Occurs when a B cell changes the immunoglobulin class it synthesizes (e.g., a B cell making IgM switches to making IgG).

Early in its life, a B cell produces IgM molecules, which are the receptors responsible for its recognition of a specific antigen. At this time, the constant region of the heavy chain is encoded by the first constant region gene, the η gene (see [Figures 41.9](#) and [41.10](#)). If the B cell later becomes a plasma cell during a humoral immune response, another deletion occurs in the cell's DNA, positioning the variable region genes (consisting of the same *V*, *D*, and *J* genes) next to a constant region gene farther away on the original DNA molecule. Such a DNA deletion results in the production of a new immunoglobulin with a different constant region of the heavy chain, and therefore a different function (see [Table 41.2](#)). However, this immunoglobulin has the same variable regions—and therefore the same antigen specificity—as the IgM produced by the parent B cell. The new immunoglobulin protein falls into one of the other four classes (IgA, IgD, IgE, or IgG), depending on which of the constant region genes is placed adjacent to the variable region genes.

41.4 recap

The humoral immune response is based on the synthesis by B cells of specific immunoglobulins. The specificity of an immunoglobulin derives from the amino acid sequence of its variable regions. B cells can make millions of immunoglobulins with different specificities by rearranging the genes that encode the variable regions of the heavy and light chains.

learning outcomes

You should be able to:

- Compare the antigen—binding site of an antibody with other molecules such as enzymes that bind other molecules.
- Describe the roles of molecules such as immunoglobulins in humoral immunity and of T cell receptors in cellular immunity.
- Compare the diversity of specific antibodies in an individual with the diversity of other biological molecules.

1. Describe the part of an antibody molecule that interacts with an antigen. How is it similar to the active site of an enzyme? How does it differ?
2. Compare immunoglobulins and T cell receptors with respect to structure and function.
3. Discuss the diversity of antibody specificities in an individual in relation to the diversity of enzymes. Does every cell in an animal contain genetic information for all of that organism's enzymes? For all of the immunoglobulins? Explain your answer.

By making antibodies, B cells are the major players in the humoral immune response. We will now turn to the cellular immune response and the T cells responsible for it.

***connect the concepts** When they occur in the coding regions of proteins, point mutations can cause silent, missense, nonsense, or frame—shift mutations (see [Figure 15.2](#)). [Key concept 17.2](#) discusses how some sequences of DNA can move within a genome.

41.5 The Cellular Adaptive Response Involves T Cells and Receptors

Two types of effector T cells (T—helper cells and cytotoxic T cells) are involved in the cellular immune response. They work along with proteins of the major histocompatibility complex (the MHC proteins), which present antigens on the surfaces of cells and contribute to the immune system's tolerance for the body's own cells.

focus your learning

In the effector phase of the humoral response, T—helper (T_H) cells activate previously unexposed B cells with the same specificity to produce antibodies.

Regulatory T cells (Tregs), which recognize self antigens, help ensure that the immune system does not attack self cells and molecules indiscriminately.

Two classes of effector T cells (cytotoxic T cells and T—helper cells) are involved in the cellular adaptive response.

Diversity in MHC molecules is very high in humans.

Like B cells, T cells possess specific membrane receptors. The T cell receptor is not an immunoglobulin, but a glycoprotein with a molecular weight of about half that of an IgG. It is made up of two polypeptide chains, each encoded by a separate gene ([Figure 41.11](#)). The two chains have distinct regions with constant and variable amino acid sequences. As in the immunoglobulins, the variable regions provide the site for specific binding to antigens. But there is one major difference: whereas an antibody can bind to an antigen whether it is present on the surface of a cell or not, a T cell receptor binds only to an antigen displayed by an MHC protein on the surface of an antigen—presenting or target cell.

Figure 41.11 A T Cell Receptor The receptors on T lymphocytes are smaller than those on B lymphocytes, but their two polypeptides contain both variable and constant regions. As with the B cell receptors, the constant regions fix the receptor in the cell membrane, while the variable regions establish the specificity for binding to antigen.

Animation 41.4 [Cellular Immune Response www.Life11e.com/a41.4](http://www.Life11e.com/a41.4)

cellular immune response Immune system response mediated by T cells and directed against parasites, fungi, intracellular viruses, and foreign tissues (grafts). (Contrast with humoral immune response.)

When a T cell is activated by contact with a specific antigen, it proliferates and forms a clone. Its descendants form clones of two types of effector T cells:

- Cytotoxic T cells, or T_C cells, recognize virus—infected or mutated cells and kill them by inducing lysis.
- T—helper cells (T_H cells, also called helper T cells) assist both the cellular and the humoral immune responses.

MHC proteins present antigen to T cells, causing recognition

Both T_H and T_C cells express T cell receptors that bind to antigen on the cell surface. But the response of each cell type to binding is quite different. T_H binding results in activation of the adaptive immune response, whereas T_C binding results in death of the cell carrying the antigen. MHC proteins form complexes with antigens on cell surfaces and assist with recognition by the T cells, so that the appropriate type of T cell binds.

The MHC proteins are cell membrane glycoproteins. Two types of MHC proteins function to present antigens to the two different types of T lymphocytes:

- **Class I MHC proteins** are present on the surface of every nucleated cell in the mammalian body. They present antigens to T_C cells. These antigens can be fragments of virus proteins in virus—infected cells or abnormal proteins made by cancer cells as a result of somatic mutations. A T_C cell with the appropriate T cell receptor binds to the MHC—antigen complex. To ensure binding, the T_C cell also has a cell surface receptor protein called CD8 that recognizes and binds to MHC I.

class I MHC proteins Cell surface proteins that participate in the cellular immune response directed against virus-infected cells.

- **Class II MHC proteins** are on the surfaces of macrophages, B cells, and dendritic cells. They present antigens to T_H cells. The three cell types ingest antigens and break them down; one of the fragments then binds to MHC II for presentation (**Figure 41.12**). A T_H cell with the appropriate T cell receptor binds to the MHC—antigen complex. To ensure binding, the T_H cell also has a cell surface receptor protein called CD4 that recognizes and binds to MHC II.

class II MHC proteins Cell surface proteins that participate in the cell–cell interactions (of T-helper cells, macrophages, and B cells) of the humoral immune response.

Figure 41.12 Macrophages Are Antigen—Presenting Cells A fragment of an antigen is displayed by MHC II on the surface of a macrophage. T cell receptors on a specific T_H cell can then bind to and interact further with the antigen—MHC II complex.

In humans there are three genetic loci for class I MHC proteins and three for class II MHC proteins. Each of these six loci has as many as 100 different alleles. With so many possible allele combinations, it is not surprising that different people are very likely to have different MHC genotypes. This is why it can be difficult to find a good “match” for organ donations. MHC proteins are “self” markers. To accomplish its role in antigen presentation, an MHC protein has an antigen— binding site that can hold a peptide of about 10–20 amino acids.

Information on MHC proteins, the cellular origins of antigens, and T lymphocytes is summarized in [Table 41.3](#).

table 41.3 The Interaction between T Cells and Antigen—presenting Cells				
presenting cell type	Antigen presented	MHC class	T cell type	T cell surface protein
Any cell	Intracellular protein fragment	Class I	Cytotoxic T cell (T _C)	CD8
Macrophages, dendritic cells, and B cells	Fragments from extracellular proteins	Class II	Helper T cell (T _H)	CD4

T—helper cells and MHC II proteins contribute to the humoral immune response

When a T_H cell survives the selection processes and binds to an antigen—presenting cell, it releases cytokines that activate the T_H cell to proliferate, producing a clone of T_H cells with the

same specificity. The steps to this point constitute the activation phase of the humoral immune response, and they occur in the lymphoid tissues. Next comes the effector phase, in which the T_H cells activate previously unexposed B cells with the same specificity to produce antibodies.

B cells are also antigen—presenting cells. B cells take up antigens bound to their surface immunoglobulin receptors by endocytosis, break them down, and display antigenic fragments on class II MHC proteins. When a T_H cell binds to the displayed antigen—MHC II complex, it releases cytokines that cause the B cell to produce a clone of plasma cells and memory cells (**Figure 41.13A**). Finally, the plasma cells secrete antibodies, completing the effector phase of the humoral immune response.

Figure 41.13 Phases of the Humoral and Cellular Immune Responses Both the (A) humoral and the (B) cellular immune responses have activation and effector phases, all of which involve T cells.

Figure 41.13 Phases of the Humoral and Cellular Immune Responses Both the (A) humoral and the (B) cellular immune responses have activation and effector phases, all of which involve T cells.

Cytotoxic T cells and MHC I proteins contribute to the cellular immune response

Class I MHC proteins play a role in the cellular immune response that is similar to the role played by class II MHC proteins in the humoral immune response. In a virus—infected or mutated cell, foreign or abnormal proteins or peptide fragments combine with class I MHC molecules. The resulting complex is displayed on the cell surface and presented to T_C cells. When a T_C cell recognizes and binds to this antigen—MHC I complex, it is activated to proliferate (**Figure 41.13B**).

In the effector phase of the cellular immune response, T_C cells recognize and bind to cells bearing the same antigen—MHC I complex. These bound T_C cells produce a substance called perforin, which ultimately results in apoptosis of the bound target cell. In addition, the T_C cells can bind to a specific receptor (called Fas) on the target cell that initiates apoptosis in that cell. These two mechanisms work in concert to eliminate the antigen—containing host cell. Because T_C cells recognize MHC proteins complexed with nonself antigens, they help rid the body of its own virus—infected or cancer cells.

Regulatory T cells suppress the humoral and cellular immune responses

A third class of T cells called **regulatory T cells (Tregs)** ensures that the immune system does not attack self cells and molecules indiscriminately. Like T_H and T_C cells, Tregs mature in the thymus gland, carry T cell receptors, and become activated if they bind to antigen—MHC complexes. But Tregs are different in one important way: the antigens that Tregs recognize are *self antigens*. The activation of Tregs causes them to secrete cytokines, which blocks the activation of T cells that are bound to the same antigen—presenting cell (**Figure 41.14**). Thus Tregs constitute another mechanism for distinguishing self from nonself.

regulatory T cells (Tregs) The class of T cells that mediates tolerance to self antigens.
--

Figure 41.14 Tregs and Tolerance A special class of T cells called regulatory T cells (Tregs) inhibits the activation of the immune system in response to self antigens.

41.5 recap

The cellular immune response acts against virus-infected or mutated body cells. Specific receptors on T cells bind to antigen-MHC complexes displayed on cell surfaces. During development, T cells are selected that recognize MHC proteins. T-helper cells bind antigens on MHC II proteins and contribute to the humoral immune response. Cytotoxic T cells bind antigens on MHC I proteins and contribute to the cellular immune response. Tregs suppress

immune responses to self antigens.

learning outcomes

You should be able to:

- Summarize the role of MHC proteins in the humoral immune response.
 - Provide reasonable speculation regarding how drugs could generate immunosuppression by targeting T—helper cells, and predict the side effects of these drugs.
 - Describe how Tregs suppress the cellular and humoral immune systems.
 - Predict consequences of inappropriate levels of activity of Tregs.
-

1. MHC proteins almost always differ among unrelated people, so organ transplants usually provoke a cellular immune response by the host, causing rejection. People receiving transplants are given a drug called cyclosporine which inhibits T cell development. How do you think cyclosporine works?
 2. When a virus infects a cell, the immune system mounts an adaptive response to this infection. What are the roles of the T cell receptor and MHC protein in this response?
 3. Cancer cells often express proteins that the body has never seen, so they are targeted by the cellular adaptive immune system. In some cancers, however, Tregs are increased in numbers and activity. Why would this indicate a poor prognosis?
-

Given the numerous and complex cellular interactions that activate the immune system and generate antibody diversity, you may have perceived many points at which the immune system could fail. We will now turn to several situations in which one or more components of this complex system malfunction.

41.6 Malfunctions in Immunity Can Be Harmful

Sometimes the immune system overreacts, as in an allergic response. Sometimes it attacks self antigens, as in autoimmune disease. And sometimes it fails to act, or acts weakly, as in immune deficiency disease.

focus your learning

Allergic reactions, which can be immediate or delayed, result from an over—stimulation of the immune response.

Allergies can be treated by desensitization.

Autoimmunity occurs when T cells bind to antigen—MHC complexes that carry self antigens.

The study of HIV has led to the development of treatments for HIV.

The immune system mounts an excessive response in allergic reactions

An allergic reaction arises when the human immune system overreacts to (is hypersensitive to) a dose of antigen. Although the antigen itself may present no danger to the host, the inappropriate immune response may produce inflammation and other symptoms, which can cause serious illness or even death. Allergic reactions are the most familiar examples of this phenomenon. Allergic reactions may involve immediate hypersensitivity or delayed hypersensitivity.

IMMEDIATE HYPERSENSITIVITY

Immediate hypersensitivity arises when an allergic individual is exposed to an antigen (in this case referred to as an allergen) from the environment, such as a food, pollen, or the venom of an insect. In response to the allergen, the individual makes large amounts of IgE. When this happens, mast cells in tissues and basophils in the blood bind the constant end of the IgE. If that individual is exposed to the same allergen again, binding of the allergen to the IgE causes the mast cells and basophils to rapidly release a large amount of histamine (**Figure 41.15**). This results in symptoms such as dilation of blood vessels, inflammation, and difficulty breathing. If not treated with antihistamines, a severe allergic reaction can lead to death. It is not known why some people produce excessive amounts of IgE in response to allergens. There is some evidence for genetic factors predisposing people to allergic responses.

immediate hypersensitivity A rapid, extensive overreaction of the immune system against an allergen, resulting in the release of large amounts of histamine. (Contrast with delayed hypersensitivity.)

Initial response: sensitization

Subsequent responses

- 4** The allergen binds to IgE on a mast cell.
- 5** Mast cells quickly release histamine, resulting in an allergic reaction.

Figure 41.15 An Allergic Reaction An allergen is an antigen that stimulates B cells to make large amounts of IgE antibodies, which bind to mast cells and basophils. When the body encounters the allergen again, these cells produce large amounts of histamine, which has harmful physiological effects.

Allergy to pollen can be treated using a process called desensitization. The process involves injecting small amounts of the allergen (typically just an extract of the offending plant tissue) into the skin—enough to stimulate IgG production but not enough to stimulate IgE production. The next time the person is exposed to the allergen, IgG binds to it, tying it up before IgE can bind it and exert its harmful effects.

Desensitization does not work well for food allergens because the IgE response to those substances is so strong that even a small amount of antigen provokes it. The best approach for those with food allergies is to avoid foods containing the allergens. This can be difficult, but food labels listing all the ingredients are helpful. Molecular biologists are beginning to identify the antigens that act as allergens, with the hope of developing vaccines or genetically modified foods that lack the allergenic epitopes.

DELAYED HYPERSENSITIVITY

Delayed hypersensitivity is an allergic reaction that does not begin until hours after exposure to an antigen. In this case the antigen is taken up by antigen-presenting cells, and a T cell response is initiated. A T_H cell produces a clone of cells that secrete various cytokines, which cause such reactions as inflammation and rash. These events take time (hence the term

“delayed”). An example is the rash that develops after exposure to poison ivy.

delayed hypersensitivity Allergic response in which a T cell clone resulting from binding to an antigen-presenting cell releases cytokines over a period of hours to days, resulting in such effects as inflammation and rash. (Contrast with immediate hypersensitivity.)

Autoimmune diseases are caused by reactions against self antigens

Errors in the selection of T cells in the thymus can result in T cells that bind to antigen-MHC complexes that carry self antigens. Although the precise origin of [autoimmunity](#) is not known, there are several hypotheses:

autoimmunity An immune response by an organism to its own molecules or cells.

Failure of negative selection. A clone of lymphocytes making antibodies against self antigens that should have been destroyed by clonal deletion is not destroyed.

Molecular mimicry. T cells that recognize a nonself antigen, such as a virus, also recognize something on a self antigen that has a similar structure.

Autoimmunity does not always result in disease, but several autoimmune diseases are common:

People with *systemic lupus erythematosus* (SLE) have antibodies to many cellular components, including DNA and nuclear proteins released from dying cells. These antinuclear antibodies can cause serious damage when they bind to normal tissue antigens and form large circulating antigen—antibody complexes, which become stuck in tissues and provoke inflammation.

People with *rheumatoid arthritis* have difficulty in shutting down a T cell response to self antigens. These patients may have low activity of CTLA4, an inhibitory protein that blocks T cells from reacting to self antigens. This results in inflammation of the joints and other tissue damage.

Hashimoto's thyroiditis is the most common autoimmune disease in women over 50. Immune cells attack thyroid tissue, resulting in fatigue, depression, weight gain, and other symptoms.

Insulin—dependent diabetes mellitus, or type I diabetes, occurs most often in children. It is caused by an immune reaction against several proteins in the cells of the pancreas that manufacture the protein hormone insulin. This reaction kills the insulin—producing cells, so people with type I diabetes must take insulin daily in order to survive.

AIDS is an immune deficiency disorder

There are several inherited and acquired immune deficiency disorders. In some individuals, T or B cells never form; in others, B cells lose the ability to give rise to plasma cells. In either case, the affected individual is unable to mount an adaptive immune response and thus lacks a major line of defense against pathogens. The T_H cell is perhaps the most central component of the immune system because of its essential roles in both the humoral and cellular immune responses (see [Figure 41.6](#)). This cell is the target of [human immunodeficiency virus \(HIV\)](#), the retrovirus that results in [acquired immune deficiency syndrome \(AIDS\)](#).

human immunodeficiency virus (HIV) Human immunodeficiency virus, the retrovirus that causes acquired immune deficiency syndrome (AIDS).

acquired immune deficiency syndrome (AIDS) Decline in immune system function due to

HIV can be transmitted from person to person in body fluids containing the virus (such as blood, semen, or vaginal fluid). The recipient tissue is either blood (by transfusion) or a mucous membrane lining an organ (the mucus contains a high concentration of lymphocytes). HIV initially infects macrophages, T_H cells, and antigen—presenting dendritic cells in the blood and tissues. At first there is an immune response to the viral infection, and T_H cells are activated. But because HIV infects the T_H cells, they are killed both by HIV itself and by T_C cells that lyse infected T_H cells. Consequently T_H cell numbers decline after the first month or so of infection. Meanwhile, the extensive production of HIV by infected cells activates the humoral immune system. Antibodies bind to HIV, and the complexes are removed by phagocytes. The HIV level in blood goes down. There is still a low level of infection, however, because of the depletion of T_H cells (**Figure 41.16**). This process reaches a low, steady—state level called the “set point.” This point varies among individuals and is a strong predictor of the rate of progression of the disease. For most people it takes 8–10 years without treatment for the more severe manifestations of AIDS to develop. In some it can take as little as a year; in others, 20 years.

Figure 41.16 The Course of an HIV Infection An HIV infection may be carried, unsuspected, for many years before the onset of symptoms.

During this dormant period, people carrying HIV generally feel fine, and their T_H cell levels are adequate for them to mount immune responses. Eventually, however, the virus destroys the T_H cells, and their numbers fall to the point where the infected person is susceptible to infections that the T_H cells would normally eliminate. These infections result in conditions such as Kaposi's sarcoma, a skin tumor caused by a herpes virus; pneumonia caused by the fungus

Pneumocystis jirovecii; and lymphoma tumors caused by the Epstein—Barr virus. These conditions result from opportunistic infections because the pathogens take advantage of the crippled immune system of the host. They lead to death within a year or two.

HIV has been intensively studied. This has resulted in the development of drugs targeted to HIV proteins, such as the reverse transcriptase that makes cDNA from the viral RNA, and the viral protease that cuts the large precursor viral protein into its final active proteins. Treatment with combinations of such drugs has had spectacular success. Getting AIDS before the 1990s was a death sentence, with few sufferers surviving beyond a year or two. Today the survival of a treated, infected person is decades longer. Unfortunately, like many medical treatments, HIV drugs are not available to all who need them—particularly in poor regions of the world where AIDS is prevalent. Since AIDS is caused by a viral infection, a vaccine would seem an appropriate preventive agent. Unfortunately, despite a huge international effort that is ongoing, a vaccine against HIV has not been developed, probably because the virus “hides out” inside cells and is prone to a high mutation rate. There are about 1.2 million deaths per year worldwide from AIDS.

41.6 recap

Failures of the immune system include allergic reactions (caused by hypersensitivity to antigens), autoimmune diseases (caused by reactions against self antigens), and immune deficiency disorders.

learning outcomes

You should be able to:

- Summarize the responses made during immediate hypersensitivity.
 - Describe how desensitization can be used to minimize allergic reactions.
 - Summarize the hypotheses that explain how autoimmunity can occur.
 - Outline experiments to test the effectiveness of an HIV vaccine.
-
1. Some people are allergic to peanuts. Outline the events that characterize the immune reactions involved.
 2. There has been recent progress in treating peanut allergy by desensitization. How does this work?
 3. A new cancer treatment involves promoting autoimmunity by designing a drug to inhibit CTLA4, a protein on T cells that normally blocks them from mounting an autoimmune response. How does this treatment work? What might be its side effects?
 4. Development of an effective HIV vaccine requires that a person being vaccinated develop both cellular and humoral immunity against HIV. What experiments would you perform to test whether both types of immunity developed in people given a potential new vaccine?

immunity?

You have seen in this chapter that lasting immunity against a pathogen can be achieved in two ways, both of which involve exposure to an antigen associated with the pathogen and the resulting production of memory cells. The first way is natural: In *Investigating Life: What Are the Mechanisms and Implications of Long Lasting Immunity?*, we showed that people exposed to virulent strains of flu viruses retain their immunity, and even increase it when exposed to less harmful flu strains. The second way is artificial: As we described in the opening story, vaccines have been spectacularly successful at inducing lasting immunity and even eradicating diseases when enough people are vaccinated. Why, then, do people refuse vaccination? There appear to be several reasons. One is complacency—the threat of disease may seem remote. For example, measles, which used to kill thousands of children every year in the United States and still does in poor countries, is no longer a highly visible threat to public health. Second, some people believe that vaccines, although exhaustively tested and proven safe, are actually unsafe and cause disease. The internet is full of such assertions. Third, false alarms have led people to dismiss vaccination advisories. The discovery of the H1N1 flu virus (swine flu) in Mexico in 2009 led to a high alert and a mass vaccination program that turned out not to be necessary. In addition, some people are suspicious of governmental programs in general. In Pakistan, a polio vaccination program was used as a ruse by officials to gain access to the home of the international terrorist Osama bin Laden. Vaccination is a scientific success in terms of bolstering immunity and eradicating disease. But like any technology, its acceptance is a political issue.

Future directions

Following activation of the immune system, many effector cells are mobilized. Most eventually die, but some survive as memory cells. Researchers are investigating how this happens. At the University of Wisconsin, Marulasiddappa Suresh and his colleagues have shown that a single transcription factor called FoxO1 plays an important role in the effector—to—memory—cell transition. This molecule is not needed for the production of effector cells, but if it is not there, memory cells do not form. The genes regulated by FoxO1 are being characterized and may hold the key to the memory cell. Meanwhile, at Yale University, Susan Kaech and her colleagues have shown that an intercellular signaling molecule, interleukin—7 (IL—7), binds to effector cells and results in changes that may allow memory cell survival. Specifically, the target cells produce a membrane channel that allows rapid uptake of glycerol, the backbone of fats. Production of fats in the memory cell may provide the energy needed for long—term survival. Understanding how memory cells form and survive may provide valuable information for the production of better vaccines.

▶ 41.1 Animals Use Innate and Adaptive Mechanisms for Defense

- Animal defenses against **pathogens** are based on the body's ability to distinguish between self and nonself.

pathogen (path' o jen) [Gk. *pathos*: suffering + *genesis*: source] An organism that causes disease.

- **Innate** (nonspecific) **defenses** are inherited mechanisms that protect the body from many kinds of pathogens. They typically act rapidly.
- **Adaptive** (specific) **defenses** respond to specific pathogens. They develop more slowly than innate defenses but are longer—lasting.
- Innate defenses evolved before adaptive defenses, and in animals there is a common signaling pathway that sets innate defenses in motion. **Review Figure 41.1**
- Many defenses are implemented by cells and proteins carried in the blood plasma and **lymph**. **Review Figure 41.2, Activity 41.1**

lymph [L. *lympa*: liquid] A fluid derived from blood and other tissues that accumulates in intercellular spaces throughout the body and is returned to the blood by the lymphatic system.

- **White blood cells** fall into two broad groups. **Phagocytes** engulf pathogens by phagocytosis. **Lymphocytes**, which include B cells and T cells, participate in adaptive responses. **Review Figure 41.3, Activity 41.2**

white blood cells Cells in the blood plasma that play defensive roles in the immune system. Also called leukocytes.

phagocyte [Gk. *phagein*: to eat + *kystos*: sac] One of two major classes of white blood cells; one of the nonspecific defenses of animals; ingests invading microorganisms by phagocytosis.

lymphocyte One of the two major classes of white blood cells; includes T cells, B cells, and other cell types important in the immune system.

▶ 41.2 Innate Defenses Are Nonspecific

- An animal's innate defenses include physical barriers such as the skin, and competing resident microorganisms known as normal flora. **Review Figure 41.4**
- The **complement system** consists of more than 20 different antimicrobial proteins that act to alter membrane permeability and kill targeted cells.
- Circulating defensive cells, such as phagocytes and **natural killer cells**, eliminate invaders.
- **Inflammation** involves activation of several types of cells and proteins that act against invading pathogens. **Mast cells release histamine**, which causes blood vessels to dilate

and become “leaky.” **Review Figure 41.5, Activity 41.3**

▶ 41.3 Adaptive Defenses Are Specific

adaptive defenses One of the two general types of defenses against pathogens. Involves antibody proteins and other proteins that recognize, bind to, and aid in the destruction of specific viruses and bacteria. Present only in vertebrate animals. (Contrast with innate defenses.)

- The adaptive immune response recognizes specific **antigens**, responds to an enormous diversity of **antigenic determinants (epitopes)**, distinguishes self from nonself, and remembers the antigens it has encountered. **Review Animation 41.1**

antigen (an' ti jun) Any substance that stimulates the production of an antibody or antibodies in the body of a vertebrate.

antigenic determinant The specific region of an antigen that is recognized and bound by a specific antibody. Also called an epitope.

- Each antibody and each T cell is specific for a single antigenic determinant. **T cell receptors** and antibodies bind to antigens and initiate an adaptive immune response.

T cell receptor A protein on the surface of a T cell that recognizes the antigenic determinant for which the cell is specific.

- The **humoral immune response** is directed against pathogens in the blood, lymph, and tissue fluids. The **cellular immune response** is directed against an antigen established within a host cell. Both responses are mediated by antigenic fragments being presented on a cell surface. **Review Focus: Key Figure 41.6**

humoral immune response The response of the immune system mediated by B cells that produces circulating antibodies active against extracellular bacterial and viral infections. (Contrast with cellular immune response.)

cellular immune response Immune system response mediated by T cells and directed against parasites, fungi, intracellular viruses, and foreign tissues (grafts). (Contrast with humoral immune response.)

- **Clonal selection** accounts for the specificity and diversity of the immune response and for **immunological memory**. **Review Figure 41.7**

clonal selection Mechanism by which exposure to antigen results in the activation of selected T- or B-cell clones, resulting in an immune response.

immunological memory The capacity to more rapidly and massively respond to a second exposure to an antigen than occurred on first exposure.

- An activated B or T lymphocyte produces **effector cells** that attack the antigen, and **memory cells** that are long-lived and rarely divide. Effector B cells are called **plasma cells** and secrete specific antibodies.

memory cells Long-lived lymphocytes produced after exposure to antigen. They persist in the body and are able to mount a rapid response to subsequent exposures to the antigen.

plasma cell An antibody-secreting cell that develops from a B cell; the effector cell of the humoral immune system.

- **Vaccination** is inoculation with modified pathogens or antigens that provoke an immune response but are not pathogenic. **Review Investigating Life: What Are the Mechanisms and Implications of Long—Lasting Immunity?**

vaccination Injection of virus or bacteria or their proteins into the body, to induce immunity. The injected material is usually attenuated (weakened) before injection and is called a vaccine.

▶ 41.4 The Humoral Adaptive Response Involves Antibodies

See Animation 41.2

- B cells are the basis of the humoral immune response. Unexposed B cells are activated by binding of antigen and by stimulation by T_H cells with the same specificity, and then form plasma cells. These cells synthesize and secrete specific antibodies.
- An antibody is an **immunoglobulin**, a tetramer of four polypeptides: two identical light chains and two identical heavy chains, each consisting of a **constant region** and a **variable region**. **Review Figure 41.8, Activity 41.4**

constant region The portion of an immunoglobulin molecule whose amino acid composition determines its class and does not vary among immunoglobulins in that class. (Contrast with variable region.)

variable region The portion of an immunoglobulin molecule or T cell receptor that includes the antigen-binding site and is responsible for its specificity. (Contrast with constant region.)

- The variable regions determine the specificity of an immunoglobulin, and the constant regions of the heavy chain determine its class. There are five classes of immunoglobulins with different body locations and functions. **Review Table 41.2**
- B cell genomes undergo random recombination of genes coding for regions of the immunoglobulin polypeptide chains so that each cell can produce a specific antibody protein. The immunoglobulin chains derive from “supergenes” that are constructed from different combinations of **V**, **D**, **J**, and **C** genes. This DNA rearrangement and rejoining yields millions of different immunoglobulin chains. **Review Figures 41.9, 41.10, Animation 41.3**
- Once a B cell becomes a plasma cell, it may undergo class switching, in which a deletion of one or more constant region genes results in the production of an immunoglobulin with a different constant region and a different function.

▶ 41.5 The Cellular Adaptive Response Involves T Cells and Receptors

See Animation 41.4

- T cells are the effectors of the cellular immune response. T cell receptors are somewhat similar in structure to the immunoglobulins, having variable and constant regions. **Review Figure 41.11**
- The genes of the major histocompatibility complex (MHC) encode membrane proteins that

bind antigenic fragments and present them to T cells. **Review Figures 41.12, 41.13**

- There are three types of T cells. **Cytotoxic T cells** (**T_C cells**) recognize and kill virus—infected or mutated cells. **T—helper cells** (**T_H cells**) assist both the cellular and humoral immune responses. Regulatory T cells (Tregs) inhibit the other T cells from mounting an immune response to self antigens. **Review Figure 41.14**

cytotoxic T (T_C) cells Cells of the cellular immune system that recognize and directly eliminate virus-infected cells. (Contrast with T-helper cells.)

▶ 41.6 Malfunctions in Immunity Can Be Harmful

- An **allergic reaction** is an inappropriate immune response caused by **immediate hypersensitivity** or **delayed hypersensitivity** to certain antigens. **Review Figure 41.15**

allergic reaction [Ger. *allergie*: altered] An overreaction of the immune system to amounts of an antigen that do not affect most people; often involves IgE antibodies.

immediate hypersensitivity A rapid, extensive overreaction of the immune system against an allergen, resulting in the release of large amounts of histamine. (Contrast with delayed hypersensitivity.)

delayed hypersensitivity Allergic response in which a T cell clone resulting from binding to an antigen-presenting cell releases cytokines over a period of hours to days, resulting in such effects as inflammation and rash. (Contrast with immediate hypersensitivity.)

- Autoimmune diseases result when the immune system produces B and T cells that attack self antigens.
- Immune deficiency disorders result from failure of some part of the immune system. **Acquired immune deficiency syndrome (AIDS)** is a disorder that arises from depletion of the T_H cells as a result of infection with **human immunodeficiency virus (HIV)**. **Review Figure 41.16**

acquired immune deficiency syndrome (AIDS) Decline in immune system function due to depletion of T_H cells and macrophages infected with HIV.

AIDS See acquired immune deficiency syndrome.

human immunodeficiency virus (HIV) Human immunodeficiency virus, the retrovirus that causes acquired immune deficiency syndrome (AIDS).

Review

- 1.1 All white blood cells originate from multipotent stem cells in the bone marrow.
- 1.5 Two classes of effector T cells (cytotoxic T cells and T—helper cells) are involved in the cellular adaptive response.
- 1.5 Diversity in MHC molecules is very high in humans.

Original Papers: Candotti, F. et al. 2012. Gene therapy for adenosine deaminase—deficient severe combined immune deficiency: Clinical comparison of retroviral vectors and treatment plans. *Blood* 120: 3635–3646.

Gaspar, H. B., A. Alessandro, P. Fulvio, C. Fabio, M. S. Hershfield and L. D. Notarangelo. 2009. How I treat ADA deficiency. *Blood* 114: 3524–3532.

Hershfield, M. S. et al. 1987. Treatment of adenosine deaminase deficiency with polyethylene glycol—modified adenosine deaminase. *New England Journal of Medicine* 316: 589–596.

Severe combined immunodeficiency (SCID) is a very rare inherited condition in which individuals show high susceptibility to viral, fungal, and bacterial infection. Left untreated, it is fatal. SCID can be caused by mutations in any of several genes, one of which codes for the enzyme adenosine deaminase (ADA). ADA is produced in all cells, but the highest levels are found in lymphocytes.

Inside lymphocytes, when DNA is metabolized, toxic deoxyadenosine is produced. When ADA is present, deoxyadenosine is converted to a nontoxic molecule. When ADA is not present, deoxyadenosine accumulates and causes cell death, especially of T cells.

There are currently three treatments for ADA—SCID. In enzyme replacement therapy (ERT), patients are injected with ADA, usually weekly. This restores normal levels of ADA (6–12 [^]mol/h/mL) and deoxyadenosine (less than 10 percent of adenine nucleotides) in blood and immune function. The table below shows the results of ERT in one patient.

Weeksafter initial treatment	Dosage Plasma ADA (mL/kg) levels (μmol/h/mL)	percent deoxyadenosine compared with all adenine nucleotides	
0	0.1	0	44
1	0.1	2	28
2	0.2	3	19
3	0.2	7	11
4	0.2	8	5
5	0.2	5	4
6	0.2	4	3

The second treatment method is hematopoietic stem cell transplantation (HSCT), in which stem cells from a donor give rise to lymphocytes that carry the normal ADA gene. These are transplanted into the patient. The greatest obstacle in HSCT is finding a donor whose cell surface markers (in this case, human leukocyte antigens, a type of MHC protein) are similar to those of the patient. To understand the significance of the matching process, 87 patients underwent HSCT with donors having various levels of “matching,” and were studied for long—term survival ([Figure A](#)).

Figure A

The third treatment for ADA—SCID, gene therapy, can be used when a matching stem cell donor is not available. Blood stem cells are removed from an ADA patient and then exposed in the lab to a viral vector that inserts the correct gene sequence for ADA into the cells. These modified cells are then returned to the patient. [Figure B](#) shows the results for one patient. The normal range of ADA activity is at least 60 nmol/10⁸ cells/min.

Figure B

Questions

1. According to the table, how many weeks of ERT therapy were needed to restore blood ADA and deoxyadenosine levels to normal? Why were weekly injections necessary? Explain your answer.
2. Summarize the survival of the patients in [Figure A](#) from each type of matched donor. Which donor category would most closely approximate what would happen with an untreated patient? Explain your

answer.

3. Most patients who are successfully treated with gene therapy also receive ERT. Explain how this would be advantageous.

Animal Reproduction

This Blue-footed booby (*Sula nebouxii*) pair is in a courtship dance.

key concepts

- [12.1 Asexual Reproduction Is Efficient but Limits Genetic Variability](#)
- [12.2 Sexual Reproduction Involves the Union of Haploid Egg and Sperm](#)
- [12.3 Male Sex Organs Produce and May Deliver Sperm](#)
- [12.4 Female Sex Organs Produce Eggs and Nurture Embryos](#)
- [12.5 Fertility Can Be Controlled](#)

No Time to Waste

Female tammar wallabies become sexually receptive and mate soon after they give birth. The resulting embryo can be born any time from a month to a year later. Humans have a set 9-month pregnancy, so this highly variable duration of pregnancy seems unusual and leads to questions of “why” and “how.” Knowing more about the development of the young wallaby, called a joey, helps. The joey is very immature when born. It crawls into its mother’s pouch (the marsupium) where it suckles and grows for up to 10 months when it is weaned.

Answering the “why” question is not difficult. Reproductive success is the currency of evolution. Reproductive success depends on how many offspring a female can produce and on the chances that those offspring survive, reproduce, and pass on their genes to the following generation. Mating soon after giving birth (as the wallaby does) can maximize the number of offspring a female produces, but it does not necessarily maximize the survival and success of those offspring. Survival of offspring in many species depends on the ability of the mother to provide maternal care. Mammalian mothers produce milk to nourish their young, and that has an enormous energy cost. Therefore the females of many mammalian species do not become fertile and sexually receptive until they have weaned their young. But, this is not true for the tammar wallaby.

The large energy investment that a tammar wallaby mother makes to successfully rear a single offspring means that giving birth while still having one joey in the pouch lowers the chances of having either of those young survive. The adaptation of this species is developmental arrest, or diapause. The fertilized egg begins to develop into an embryo, but at an early stage of development its cell divisions cease, its metabolism decreases, and it remains in the uterus without implanting in the uterine lining as long as the previous offspring is suckling. If that offspring dies or is weaned, the quiescent embryo in the uterus is activated, implants in the uterine lining, and continues its development. Having an embryo ready to go when conditions are right is a way of maximizing reproductive success, but the “how” question remains.

What signal controls the breaking of diapause in the tammar wallaby?

42.1 Asexual Reproduction Is Efficient but Limits Genetic Variability

When we think of reproduction, we think of sex, but many species can reproduce asexually—the offspring are exact genetic copies of the parents. Most of the animal species that reproduce asexually are invertebrates living in rather constant environments. However, examples of asexual reproduction do occur in vertebrates. Reproduction by female sharks living in aquaria with no males have been reported. The natural habitat of these fish is the open ocean where potential mates might not be readily available. Asexual reproduction is efficient because no time or energy is wasted on mating and every member of the population can convert resources into offspring.

focus your learning

Asexual reproduction does not generate genetic diversity.

Budding and regeneration are forms of asexual reproduction.

Parthenogenesis is the development of offspring from unfertilized eggs.

You can demonstrate to yourself the efficiency of asexual reproduction with a thought exercise. Start with two females, one reproducing sexually and one asexually. Assume that each can have two offspring, but in the case of the sexually reproducing female, one will be a male. Also, assume that in each subsequent generation all of the females (mothers and daughters) will have two offspring each. In the first generation, the asexually reproducing female will have two daughters who can then each have two female offspring. Thus in the next generation there will be three females having two offspring each. The sexually reproducing female will give rise to only one female, so in the next generation there will be two females reproducing having two offspring each—only one of which is female. Run this thought exercise through four or five cycles and compare the numbers of offspring produced.

Asexual reproduction limits genetic diversity

A disadvantage of asexual reproduction is that the offspring are genetically identical to one another and to their parents. Thus asexual reproduction does not generate genetic diversity. Genetic diversity is the raw material that enables natural selection to shape adaptations in response to environmental change. When environmental changes occur, lack of genetic diversity can be disadvantageous to a population. Asexual reproduction is, however, a good way to preserve a successful genotype in a stable environment. Aphids are an example of a species that has it both ways (**Figure 42.1**). In the spring, the aphids that hatch on rose bushes from overwintering eggs are all females. Each of those aphids reproduces asexually to produce many more females—all genetically identical. This is a time when there is plenty of food and the environment is stable. When the conditions change due to drought or season, the females still reproduce asexually, but some of the offspring develop into males. The ensuing sexual reproduction introduces genetic variation into the eggs that will remain dormant until favorable conditions return.

Figure 42.1 Aphids Are Sexual and Asexual When environmental conditions are favorable, such as in a rose garden in the summer, aphids make the most of resources by rapidly reproducing asexually. They are actually making identical copies of themselves. But when environmental conditions are unsure, such as in the fall, aphids reproduce sexually and thereby increase their genetic diversity in the face of changing, unpredictable conditions.

Three common modes of asexual reproduction are budding, regeneration, and parthenogenesis.

Budding and regeneration produce new individuals by mitosis

Many simple multicellular animals produce offspring by **budding**. New individuals form as outgrowths or buds from the bodies of older animals. A bud grows by mitotic cell division, and the cells differentiate before the bud breaks away from the parent (**Figure 42.2A**). The bud is genetically identical to the parent, and it may grow as large as the parent before it becomes independent.

bud A protuberance on a stem that contains an undeveloped leaf, shoot, or flower.

(A) *Hydra littoralis*

(B) *Linkia multifora*

Figure 42.2 Two Forms of Asexual Reproduction (A) Budding: a new individual forms as an outgrowth from an adult hydra. **(B)** Regeneration: a single severed arm and a piece of the central disc of a mature sea star can regenerate into an entire animal.

Regeneration is usually thought of as the replacement of damaged tissues or lost limbs, but in some cases pieces of an organism can regenerate complete individuals. Echinoderms, for example, have remarkable abilities to regenerate. If sea stars are cut into pieces, each piece that includes an arm and a portion of the central disc can grow into a new animal (**Figure 42.2B**). In the early 1900s oyster fishermen in Narragansett Bay tried to eliminate the sea stars that were preying on their oysters. Whenever they encountered sea stars, they cut them up with their knives and threw them back into the water. As a result, the sea star population increased explosively. A variant of regeneration called fission involves the animal splitting in half with each half growing into a whole individual. An example is sea anemones.

regeneration The development of a complete individual from a fragment of an organism.

Regeneration can occur when an animal is broken by an outside force such as wave action in the intertidal zone. In some cases, breakage occurs in the absence of external forces. Some species of segmented marine worms develop segments with rudimentary heads bearing sensory organs. The segments then break apart and each one forms a new worm.

Parthenogenesis is the development of unfertilized eggs

Not all eggs must be fertilized to develop. A common mode of asexual reproduction in arthropods (including aphids) is the development of offspring from unfertilized eggs. This phenomenon, called **parthenogenesis**, also occurs in some species of fish, amphibians, and reptiles. Most species that reproduce parthenogenetically also engage in sexual reproduction or at least sexual behavior at other times. In some species, parthenogenesis is part of the mechanism that determines sex. In honeybees (as well as in most ants and wasps), males develop from unfertilized eggs and are haploid, whereas females develop from fertilized eggs and are diploid.

parthenogenesis [Gk. *parthenos*: virgin] Production of an organism from an unfertilized egg.

Parthenogenetic reproduction in some species requires sexual behavior even though sperm are not involved and eggs are not fertilized. David Crews and his students at the University of Texas extensively investigated one such case, that of parthenogenetic reproduction in a species of whiptail lizard. There are no males of this species. Females can act as males, engaging in all aspects of courtship display and mating, although no sperm are produced or transferred ([Figure 42.3](#)). Whether a specific female acts as a female or as a male depends on cyclical hormonal states. When estrogen levels are high, she acts as a female. When her progesterone levels peak, she acts as a male. The stimulation resulting from the sexual activity triggers the release of eggs from the ovaries of the acting female.

(A) Sexual behavior in parthenogenetic whiptail lizards

(B) Sex role in whiptail lizards is under hormonal control

Figure 42.3 Asexual Reproduction May Require Sexual Behavior (A)

Parthenogenetic whiptail lizards are all females, but they take turns acting the male role in reproductive behavior. The stimulation from sexual behavior is necessary for ovulation to occur. **(B)** The cycling of ovarian hormones determines the role an individual whiptail plays.

Q: What selective advantages could accrue to a bisexual species becoming unisexual?

42.1 recap

Many species of animals, especially invertebrates, can reproduce asexually through budding, regeneration, or parthenogenesis. Asexual reproduction is an efficient use of resources but does not produce genetic diversity.

learning outcomes

You should be able to:

- Describe circumstances that make asexual reproduction disadvantageous.
- Describe the characteristics of the different types of asexual reproduction.
- Explain conditions that would favor parthenogenesis over other forms of asexual reproduction.

-
1. What is similar about budding and regeneration but **not** parthenogenesis?
 2. Is global climate change likely to have a more negative impact on a species that reproduces asexually or one that reproduces sexually?
 3. The Komodo dragon is a very large, sexually breeding species of lizard that lives on the Indonesian island of Komodo. A young Komodo dragon named Flora was raised alone for many years in the London Zoo. One year after reaching sexual maturity, she laid a clutch of eggs that produced several baby dragons, all males. How did Flora reproduce? What advantage might this ability have for an island-dwelling species? Why is it significant that the offspring were all male?

Asexual reproduction is an efficient way to use resources. Since most animals reproduce sexually, however, the genetic diversity produced by sexual reproduction must confer a tremendous advantage.

42.2 Sexual Reproduction Involves the Union of Haploid Egg and Sperm

Given the inefficiency of sexual reproduction, its prevalence is somewhat surprising. In most sexually reproducing species, the sex ratio is 1:1 and therefore half the population (males) cannot produce offspring. And mating behaviors involve costs and risks. Costs include time and energy spent finding, attracting, and competing for a mate, as well as the “opportunity costs” of detracting from other activities such as feeding and caring for existing offspring. Risks include increased exposure to predation and the potential for physical damage. Despite these disadvantages, most eukaryotic organisms reproduce sexually. Thus it would seem that the production of genetic diversity is an evolutionary advantage that can overwhelm the cost of sex (see [Key Concepts 20.2](#) and [20.4](#)).

focus your learning

In spermatogenesis, four haploid sperm are produced from each primary spermatocyte.

Oogenesis involves asymmetrical division of cytoplasm.

Specific recognition molecules mediate interactions between sperm and eggs in sea urchins.

Hermaphrodites can function both as male and as female.

Organisms in aquatic environments generally have external fertilization and engage in spawning to bring eggs and sperm together.

Mechanisms of internal fertilization are highly diverse.

Hermaphrodites can function both as male and as female.

Sexual reproduction requires the joining of two haploid sex cells to form a diploid individual. These haploid cells, or **gametes**, are produced through gametogenesis, a process that involves meiotic cell divisions. Two events in meiosis contribute to genetic diversity: crossing over between homologous chromosomes and the independent assortment of chromosomes (see [Key Concepts 11.5](#) and [12.1](#)). Mating behavior itself also contributes to genetic diversity. The genetic variation among the gametes of a single individual and the genetic variation between any two parents produce an enormous potential for genetic variation between any two offspring of a sexually reproducing pair of individuals.

gamete (gam' eet) [Gk. *gamete/gametes*: wife, husband] The mature sexual reproductive cell: the egg or the sperm.

Sexual reproduction in animals consists of three fundamental steps:

- **Gametogenesis**: making gametes

gametogenesis (ga meet' oh jen' e sis) The specialized series of cellular divisions that leads to the production of gametes. Called oogenesis when referring to processes in the ovary and spermatogenesis in the testis.

- . **Spawning** or **mating**: bringing gametes together

spawning See external fertilization.

mating The joining of individuals for the purpose of reproduction.

- . **Fertilization**: fusing gametes

fertilization Union of gametes. Also known as syngamy.

The process of gametogenesis is similar across sexually reproducing animal species. Processes of fertilization are also quite similar in widely different species. Therefore, while our discussion of gametogenesis will focus generally on mammals, and our discussion of fertilization will feature sea urchins, the facts would not be dramatically different were we to consider many other animal groups. Adaptations for spawning and mating, in contrast, show incredible anatomical, physiological, and behavioral diversity across species.

Gametogenesis produces eggs and sperm

Gametogenesis occurs in the gonads: male **testes** (singular **testis**) and female **ovaries** (singular **ovary**). The tiny male gametes, **sperm**, move by beating their flagella. The larger female gametes, **eggs** or ova (singular **ovum**), are nonmotile.

testis (tes' tis) (plural: testes) [L. *testis*: witness] The male gonad; the organ that produces the male gametes.

sperm [Gk. *sperma*: seed] The male gamete.

egg In all sexually reproducing organisms, the female gamete; in birds, reptiles, and some other vertebrates, a structure within which early embryonic development occurs. (See also amniote egg, ovum.)

Gametes are produced from **germ cells**, which have their origin in early cell divisions of the embryo and remain distinct from all the other cells of the body (the somatic cells). Germ cells are sequestered in the body of the embryo until its gonads begin to form. The germ cells then migrate to the developing gonads, where they take up residence and proliferate by mitosis, producing **spermatogonia** (singular **spermatogonium**) in males and **oogonia** (singular **oogonium**) in females (**Figure 42.4**). Spermatogonia and oogonia are diploid, multiply by mitosis, and are stem cells. They are self-regenerating, and they also produce progeny—spermatocytes and oocytes—that will enter the next stage of gametogenesis.

germ cell [L. *germen*: to beget] A reproductive cell or gamete of a multicellular organism. (Contrast with somatic cell.)

sperm [Gk. *sperma*: seed] The male gamete.

spermatogonium (plural: spermatogonia) In animals, the diploid progeny of a germ cell in males.

(A) Spermatogenesis

(B) Oogenesis

Figure 42.4 Gametogenesis Male and female germ cells proliferate by mitosis and produce diploid spermatogonia and oogonia that mature into primary spermatocytes and oocytes before entering meiosis. **(A)** Spermatogonia continue to divide by mitosis in adults, producing a steady supply of spermatocytes that divide meiotically to produce haploid spermatids, which differentiate into sperm. In many species, the progeny of spermatocytes remain in contact through cytoplasmic bridges until the sperm mature. **(B)** In mammals, oogonia cease division in the embryo, and primary oocytes remain arrested in prophase I of meiosis until they are ovulated and fertilized. Each oocyte will produce one haploid ootid, which matures into an egg.

In the next stage of gametogenesis, meiotic cell division reduces the chromosomes to the haploid number (see [Key Concept 11.5](#)). The progeny of the spermatogonia and oogonia that enter meiosis are **primary spermatocytes** and **primary oocytes**. The steps of meiosis are similar in males and females, but there are important sex differences in gametogenesis.

primary spermatocyte The diploid progeny of a spermatogonium; undergoes the first meiotic division to form secondary spermatocytes.

primary oocyte (oh' eh site) [Gk. *oon*: egg + *kytos*: container] The diploid progeny of an oogonium. In many species, a primary oocyte enters prophase of the first meiotic division, then remains in developmental arrest for a long time before resuming meiosis to form a

secondary oocyte and a polar body.

SPERMATOGENESIS

The initial proliferation of male germ cells into spermatogonia proceeds by mitosis in the embryo. But throughout the male life span, spermatogonia continue to divide by mitosis, with one daughter cell retaining the self-regenerating capacity of a spermatogonium while the other daughter cell becomes a primary spermatocyte. As illustrated in [Figure 42.4A](#), primary spermatocytes then undergo the first meiotic division—the reduction division—to form two haploid [secondary spermatocytes](#).

secondary spermatocyte One of the products of the first meiotic division of a primary spermatocyte.

The second meiotic division produces four haploid [spermatids](#) for each primary spermatocyte that enters meiosis. In mammals, the progeny of primary spermatocytes remain connected by cytoplasmic bridges after each division.

spermatid One of the products of the second meiotic division of a primary spermatocyte; four haploid spermatids, which remain connected by cytoplasmic bridges, are produced for each primary spermatocyte that enters meiosis.

One reason that mammalian spermatocytes remain in cytoplasmic contact throughout their development is the asymmetry of sex chromosomes in males. Half the secondary spermatocytes receive an X chromosome, the other half a Y chromosome. The Y chromosome contains fewer genes than the X chromosome, and some of the products of genes found only on the X chromosome are essential for spermatocyte development. By remaining in cytoplasmic contact, all four spermatocytes can share the gene products of the X chromosomes, although only half of them have an X chromosome.

A spermatid bears little resemblance to a mature sperm. Through further differentiation the spermatid becomes compact, streamlined, and develops a flagellum to become motile. We will look at the production of human sperm in [Key Concept 42.3](#).

OOGENESIS

Oogonia, like spermatogonia, proliferate through mitosis (see [Figure 42.4B](#)). The resulting primary oocytes immediately enter prophase of the first meiotic division. In many species, including humans, the oocyte experiences developmental arrest at this point and may remain in that state for days, months, or years. In the human female, this period of arrest is at least 10 years (i.e., until puberty), and some primary oocytes remain in prophase I for over 50 years (i.e., until menopause). In contrast, spermatogenesis continues, uninterrupted, to completion once the primary spermatocyte has differentiated.

During the prolonged prophase I, or shortly before it ends, the primary oocyte grows larger through increased production of ribosomes, RNA, cytoplasmic organelles, and energy stores. At this point the primary oocyte acquires all the energy, raw materials, and RNA that the egg will need to survive its first cell divisions after fertilization. In fact, the nutrients in the egg must maintain the embryo until it is either nourished by the maternal circulatory system or can feed on its own.

When a primary oocyte resumes meiosis, its nucleus completes the first meiotic division near the surface of the cell. The daughter cells of this division receive grossly unequal shares of cytoplasm. This asymmetry represents another major difference from spermatogenesis, in which

cytoplasm is apportioned equally. The daughter cell that receives almost all the cytoplasm becomes the **secondary oocyte**, and the one that receives almost none forms the **first polar body** (see [Figure 42.4B](#)).

secondary oocyte In oogenesis, the daughter cell of the first meiotic division that receives almost all the cytoplasm. (See *also* first polar body.)

first polar body The small daughter cell from the first meiotic division of a primary oocyte.

The second meiotic division—that of the large, secondary oocyte—is accompanied by asymmetrical division of the cytoplasm. One daughter cell forms the large, haploid **ootid** that eventually differentiates into a mature egg, and the other forms the **second polar body**. In most species the polar bodies rapidly degenerate, so the end result of oogenesis is only one mature egg for each primary oocyte that entered meiosis. However, that egg is a large, well-provisioned cell. In a few species the polar bodies have evolved specialized functions. In some species that reproduce parthenogenetically, a polar body can fuse with the egg to restore the diploid number of chromosomes. In some insect species the polar bodies form organs with specialized functions. An example is scale insects in which cells derived from the polar bodies form a container for endosymbiotic bacteria that the insects require for life.

ootid In oogenesis, the daughter cell of the second meiotic division that differentiates into the mature ovum.

second polar body In oogenesis, the daughter cell of the second meiotic division that subsequently degenerates. (See *also* ootid.)

A second period of arrested development occurs after the first meiotic division forms the secondary oocyte. The egg may be expelled from the ovary in this condition. In many species, including humans, the second meiotic division is not completed until the egg is fertilized by a sperm.

Fertilization is the union of sperm and egg

The union of the haploid sperm and the haploid egg (fertilization) creates a single diploid cell, a **zygote**, which will develop into an embryo. Fertilization does more than just restore the full genetic complement of the animal. The processes associated with fertilization help the egg and sperm get together, prevent the union of the sperm and egg of different species, and guarantee that only one sperm will enter and activate the egg. Fertilization involves a complex series of events:

zygote (zye' gote) [Gk. *zygotos*: yoked] The cell created by the union of two gametes, in which the gamete nuclei are also fused. The earliest stage of the diploid generation.

- . The sperm and the egg chemically recognize each other.
- . The sperm is activated, enabling it to gain access to the cell membrane of the egg.
- . The cell membrane of the egg fuses with the cell membrane of a single sperm.
- . The egg blocks entry of additional sperm.
- . The egg is metabolically activated and stimulated to start development.

. The egg and sperm nuclei fuse to create the diploid nucleus of the zygote.

SPECIFICITY IN SPERM-EGG INTERACTIONS

Specific recognition molecules mediate interactions between sperm and eggs. These molecules ensure that the activities of sperm are directed toward eggs and not other cells, and they help prevent eggs from being fertilized by sperm from the wrong species. The latter function is particularly important in aquatic species that release eggs and sperm into the surrounding water where the eggs can readily be exposed to sperm of other species. The sea urchin is a good example of such a species, and sea urchin fertilization has been well studied.

Sea urchin eggs release chemical attractants that increase the motility of sperm and cause them to swim toward the egg. These chemical attractants are species-specific. For example, eggs of one species of sea urchin release a specific peptide consisting of 14 amino acids. This peptide binds to receptors present on sperm of the same species. The sperm respond by increasing their mitochondrial respiration and motility. Before exposure to the peptide, the sperm swim in tight little circles, but after binding to the peptide, they swim energetically up the concentration gradient of the peptide until they reach the egg that is releasing it.

When sperm reach an egg, they must get through two protective layers before they can fuse with the egg cell membrane. The eggs of sea urchins are covered with a jelly coat that surrounds a proteinaceous **vitelline envelope** (**Figure 42.5A**). The success of a sperm's assault on these protective layers depends on a membrane-enclosed structure at the front of the sperm head called an **acrosome**.

vitelline envelope The inner, proteinaceous protective layer of a sea urchin egg.

acrosome (a' krow soam) [Gk. *akros*: highest + *soma*: body] The structure at the forward tip of an animal sperm, which is the first to fuse with the egg membrane and enter the egg cell.

(B) Fertilization of the sea urchin egg

Figure 42.5 Fertilization of the Sea Urchin Egg (A) Sea urchin eggs are protected by a jelly layer and a proteinaceous vitelline envelope. Sperm must penetrate both to reach the egg cell membrane. Many sperm attach to the vitelline envelope, but only the first one to reach the egg cell membrane achieves fertilization. The numbers match structures with the events shown in (B). (B) The acrosomal reaction allows a sea urchin sperm to recognize an egg of the same species and pass through its protective layers. Enzymes from the egg's cortical granules trigger the slow block to polyspermy.

Animation 42.1 Fertilization in a Sea Urchin Egg www.Life11e.com/a42.1

The acrosome contains enzymes and other proteins. When a sperm makes contact with an egg of its own species, substances in the jelly coat trigger an acrosomal reaction, which begins with the breakdown of the cell membrane covering the sperm head and the underlying acrosomal membrane (**Figure 42.5B**). The acrosomal enzymes are released and digest a hole through the jelly coat.

As a result of the polymerization of actin triggered by the acrosomal reaction, an acrosomal process extends out of the head of the sperm. The acrosomal process is coated with species-specific recognition molecules called **bindin**, and there are bindin receptors on the vitelline envelope of the egg. The interaction of bindin with their receptors enables the sperm to contact the egg cell membrane. That contact results in fusion of the sperm and egg cell membranes and the formation of a fertilization cone that engulfs the sperm head, bringing it into the egg cytoplasm. The sperm mitochondria, which largely constitute the midpiece of the sperm, are also drawn into the egg cytoplasm, but they degrade and disappear; this means that the mitochondria and ***mitochondrial genes** of the new urchin are derived only from the egg.

bindin Species specific recognition molecule on the sperm acrosomal process.

mitochondria (my' toe kon' drie uh) (singular: mitochondrion) [Gk. *mitos*: thread + *chondros*: grain] Energy-generating organelles in eukaryotic cells that contain the enzymes of the citric acid cycle, the respiratory chain, and oxidative phosphorylation.

In animals that practice internal fertilization, mating behaviors help guarantee species specificity, but egg-sperm recognition mechanisms still exist. The mammalian egg is surrounded by a thick layer called the cumulus consisting of a loose assemblage of maternal cells in a gelatinous matrix (**Figure 42.6**). Beneath the cumulus is a glycoprotein envelope called the zona pellucida, which is functionally similar to the vitelline envelope of sea urchin eggs. Mammalian sperm become activated when they are deposited in the female reproductive tract, and they are then capable of an acrosomal reaction should they encounter an egg. An activated sperm can penetrate the cumulus and interact with the zona pellucida.

Figure 42.6 Barriers to Sperm This human egg, like other mammalian eggs, is surrounded by the cumulus and zona pellucida. Sperm must penetrate both to fertilize

the egg. Only one sperm will penetrate the zona pellucida and fuse with the egg cell membrane.

Q: What would be the consequences of two sperm fertilizing the egg?

Unlike the jelly coat of sea urchin eggs, the cumulus of mammalian eggs does not trigger the acrosomal reaction. When sperm make contact with the zona pellucida, a species-specific glycoprotein binds to recognition molecules on the head of the sperm. This binding triggers the acrosomal reaction, releasing acrosomal enzymes that digest a path through the zona pellucida. When the sperm head reaches the egg cell membrane, other proteins facilitate its adhesion to and fusion with the egg cell membrane.

BLOCKS TO POLYSPERMY

The fusion of the sperm and egg cell membranes and the entry of the sperm into the egg initiate a programmed sequence of events. The first responses to sperm entry are **blocks to polyspermy**: mechanisms that prevent more than one sperm from entering the egg. Survival of the embryo is unlikely if more than one sperm enters the egg. The sperm contributes a haploid set of chromosomes, so an extra set would disrupt the mitotic division of the egg and subsequent cells. In addition, in most mammals the sperm contributes a centriole to the fertilized egg, and the ***centriole forms the centrosome** which is critical for organizing the mitotic spindle. Having two centrosomes would disrupt mitosis of the fertilized egg.

Blocks to polyspermy have been studied extensively in sea urchin eggs, which can be fertilized in a dish of seawater. Within seconds after the sperm membrane contacts the egg membrane, an influx of sodium ions changes the electric charge difference across the egg cell membrane. This fast block to polyspermy prevents the fusion of any other sperm with the egg cell membrane, but it is transient. The change in membrane electric charge lasts only about a minute, but that is enough time to allow a slower block to sperm entry to develop.

The slow block to polyspermy involves converting the vitelline envelope to a physical barrier that sperm cannot penetrate. Before fertilization, the vitelline envelope is bonded to the egg cell membrane. Just under the cell membrane are vesicles called cortical granules (see [Figure 42.5](#)) which contain enzymes and other proteins.

The sea urchin egg, like all animal cells, sequesters calcium in its endoplasmic reticulum. Sperm entry into the egg stimulates the release of calcium ions from the endoplasmic reticulum and into the egg cytosol. This increase in cytosolic calcium causes the egg's cortical granules to fuse with the cell membrane and release their contents. Cortical granule enzymes break the bonds between the vitelline envelope and the cell membrane, and other proteins released from the cortical granules attract water into the space between them. As a result, the vitelline envelope rises to form a fertilization envelope. Cortical granule enzymes also degrade sperm-binding molecules on the surface of the fertilization envelope and cause it to harden, thus preventing additional sperm from contacting the egg cell membrane.

In mammalian eggs, sperm entry does not cause a rapid change in membrane potential, but it does trigger a release of calcium from the endoplasmic reticulum. As in the sea urchin egg, increased calcium causes the cortical granules to fuse egg with the egg cell membrane. A fertilization envelope does not form around the mammalian egg, but the cortical granule enzymes destroy the sperm-binding molecules in the zona pellucida. The rise in cytosolic calcium also signals the egg to complete meiosis. The stage is set for the first cell division.

Spawning and mating behaviors get eggs and sperm together

As you have just seen, sexual reproduction requires the production of haploid gametes (gametogenesis) and the joining together of those gametes to form a diploid zygote (fertilization). Spawning and mating behaviors get eggs and sperm close enough together that fertilization can occur. Fertilization can occur externally or internally.

EXTERNAL FERTILIZATION

In an aquatic environment, animals can bring their gametes together by simply releasing them into the water. This practice, called spawning, results in [external fertilization](#). Many aquatic animals are not very mobile, but they produce huge numbers of gametes that can travel far from the point of release. A female oyster, for example, will release millions of eggs when she spawns, and the number of sperm produced by a male oyster is astronomical.

external fertilization The release of gametes into the environment; typical of aquatic animals. Also called spawning. (Contrast with internal fertilization.)

Numbers alone, however, do not guarantee that gametes will meet. The reproductive activities of the males and females of a population must be synchronized, since released gametes have a limited life span. Seasonal breeders may use day length, changes in temperature, or changes in weather to time the production and release of their gametes. Mutual stimulation is also important. Release of gametes into the water by one individual can stimulate others to spawn.

Behavior can play an important role in bringing gametes together even when fertilization is external. Many species travel great distances to congregate with potential mates and release their gametes at the same time in a suitable environment. Many salmon are an extreme example. They hatch and develop in freshwater streams and then migrate to the ocean, where they remain for years. When they are mature and ready to spawn, they travel hundreds of miles back to and then up the stream to the region where they hatched. Males and females expend great amounts of energy to swim up the streams to the spawning grounds, where they pair up, prepare a depression in the streambed gravel, and together release their sperm and eggs. As the gametes drift down into the gravel, fertilization occurs.

INTERNAL FERTILIZATION

Terrestrial animals cannot simply release their gametes into the environment. Sperm can move only through liquid, and delicate gametes released into air would dry out and die. Most terrestrial animals avoid these problems by [internal fertilization](#), the release of sperm into the female reproductive tract. Some aquatic animals also practice internal fertilization, but it is ubiquitous in terrestrial animals.

internal fertilization The release of sperm into the female reproductive tract; typical of most terrestrial animals. (Contrast with external fertilization.)

Animals have evolved an astonishing diversity of behavioral and anatomical adaptations for internal fertilization. The reproductive organs together are the animal's [genitalia](#). Gametogenesis occurs in the gonads, which are the [primary sex organs](#). All additional components of an animal's genitalia are called [accessory sex organs](#). The internal accessory sex organs include a variety of glands, tubules, ducts, and other structures. External accessory sex organs are referred to as the external genitalia. In males of many species, the external genitalia includes a [penis](#) that enables the male to deposit sperm in the female's [vagina](#), the entry to her reproductive tract.

genitalia The reproductive organs, especially the external accessory sex organs.

primary sex organs Testes and ovaries.

accessory sex organs Anatomical structures that allow transfer of sperm from male to female for internal fertilization. (Contrast with primary sex organs.)

penis An accessory sex organ of male animals that enables the male to deposit sperm in the female's reproductive tract.

vagina (vuh jine' uh) [L. sheath] In female animals, the entry to the reproductive tract.

Copulation is the physical joining of male and female accessory sex organs. Most male insects copulate and transfer sperm to the female's vagina through a penis. The external genitalia of insects often have species-specific shapes that match in a lock-and-key fashion to ensure a tight, secure fit between the mating pair during the prolonged period of sperm transfer. In some insect species in which females mate with more than one male, the male external genitalia includes elaborate structures that can scoop sperm deposited by other males out of the female's reproductive tract, replacing it with his own.

copulation Reproductive behavior that results in a male depositing sperm in the reproductive tract of a female.

Transfer of sperm in internal fertilization can also be indirect. Males of many invertebrate species (e.g., mites and scorpions) and a few vertebrates (e.g., salamanders) deposit spermatophores— packets of sperm protected from desiccation—in the environment. When a female mite encounters a spermatophore from a potential mate, she straddles it and opens a pair of plates in her abdomen so that the tip of the spermatophore enters her reproductive tract and allows the sperm to enter.

Male squid and spiders play a more active role in spermatophore transfer. The male spider secretes a drop containing sperm onto a bit of web, then uses a special structure on his foreleg to pick up the sperm-containing web and insert it through the female's genital opening. Some male squid use one specialized tentacle to pick up a spermatophore and insert it into the female's genital opening.

Some individuals can function as both male and female

In most species, gametes are produced by individuals that are either male or female. Species that have separate male and female members are referred to as **dioecious** (Greek, "two houses"). In some species, however, a single individual may produce both sperm and eggs. Such species are **monoecious** ("one house"), or **hermaphroditic**.

dioecious (die eesh' us) [Gk. *di*: two + *oikos*: house] Pertaining to organisms in which the two sexes are "housed" in two different individuals, so that eggs and sperm are not produced in the same individuals. Examples: humans, fruit flies, date palms. (Contrast with monoecious.)

monoecious (mo nee' shus) [Gk. *mono*: one + *oikos*: house] Pertaining to organisms in which both sexes are "housed" in a single individual that produces both eggs and sperm. (In some plants, these are found in different flowers within the same plant.) Examples include corn, peas, earthworms, hydras. (Contrast with dioecious.)

hermaphroditism (her maf' row dite ism) The coexistence of both female and male sex organs in the same organism.

Almost all invertebrate groups contain some hermaphroditic species. An earthworm is an example of a simultaneous hermaphrodite, meaning an individual is both male and female at the same time. When two earthworms mate, they exchange sperm, and as a result the eggs of each

are fertilized (see [Figure 32.12C](#)). Some vertebrates are sequential hermaphrodites, meaning an individual may function as a male or a female at different times in its life. An example is the anemone fish, or clown fish, a species that lives in small groups within large sea anemones ([Figure 42.7](#)). All anemone fish are born male. The largest fish in a group becomes a functional female. If that fish is removed from the group, the next-largest male becomes a female. The second-largest fish in the group is the only male in breeding condition. The reverse situation also exists in some species where a large dominant male controls a harem of females. If the male is removed, the largest female becomes the male in the group.

Figure 42.7 When Size Determines Sex Anemonefish (also known as clownfish) live in groups of about a dozen centered on a single sea anemone. All anemone fish are born male; the largest fish in the group becomes a functional female. Thus a fish may function as a male and as a female at different times in its life.

What is the evolutionary advantage of hermaphroditism? Some simultaneous hermaphrodites, such as parasitic tapeworms, have a low probability of meeting a potential mate—an individual tapeworm may be the only one in its host. Tapeworms can fertilize their own eggs, but most simultaneous hermaphrodites must mate with another individual. Because every simultaneous hermaphrodite is both male and female, however, the probability of encountering a possible mate doubles. In some sequential hermaphrodites, siblings are all male or all female at the same time, thus reducing the incidence of inbreeding.

The evolution of vertebrate reproductive systems parallels the move to land

The earliest vertebrates evolved in aquatic environments. The closest living relatives of those earliest vertebrates are modern-day fishes. They remain exclusively aquatic, and most practice external fertilization. The most primitive fishes, the lampreys and hagfish, simply release their gametes into the environment. In most fishes, however, mating behaviors bring females and males into close proximity at the time of gamete release. In sharks and rays, fins have evolved into claspers that hold the male and female together and enable sperm to be transferred directly into the female reproductive tract.

Amphibians were the first vertebrates to live in terrestrial environments. They dealt with the challenge of a dry environment by returning to water to reproduce, as most amphibians still do today.

Reptiles were the first vertebrate group to solve the problem of reproduction in the terrestrial environment (**Figure 42.8**). Their solution was the amniote egg (see **Figure 32.19A**). A hard or leathery shell protects the embryo and impedes water loss while allowing the diffusion of oxygen into the egg and carbon dioxide out of the egg. The eggshell creates an obvious problem for fertilization. Sperm cannot penetrate the shell, so they must reach the egg before the shell forms. Hence internal fertilization and the evolution of accessory sex organs were necessary for the evolution of the amniote egg.

Figure 42.8 The Shelled Egg The terrestrial environment is desiccating. Therefore, the shelled egg was a major evolutionary step that allowed reptiles to reproduce in the terrestrial environment. (A) A female banded krait has deposited her eggs in the sand. (B) The shelled egg requires that sperm meet egg before the shell forms. Therefore reptiles must practice internal fertilization, as these European bee-eaters are doing.

Male snakes and lizards have paired hemipenes (hemipenis, sing.), which can be engorged with blood and thereby extruded from the male's body. Only one hemipenis is inserted into the female's reproductive tract. It is usually rough or spiny at the end to achieve a secure hold while sperm are transferred down a groove on its surface. Retractor muscles pull the hemipenis back into the male's body when mating is completed. Some evolutionarily ancient bird species have erectile penises that channel sperm along a groove into the female's reproductive tract. Birds with more recent evolutionary origins, however, do not have erectile penises; instead, the male and female simply bring their genital openings (cloacae, sing. cloaca) close together to transfer sperm. Usually this involves the male standing on the female's back (see **Figure 42.8B**).

All mammals practice internal fertilization. Then, all except the prototherian mammals retain the developing embryo for some time in the female reproductive tract. Prototherian mammals (the monotremes; see **Figure 32.26**) lay eggs. The other mammals (the therians) vary enormously as to the developmental stage of their offspring at the time of birth. As you saw at the beginning of the chapter, the tammar wallaby is extremely immature at birth. By comparison, a horse foal can stand up soon after birth and is able to run within hours.

Animals with internal fertilization are distinguished by where the embryo develops

Two patterns of care and nurture of the embryo have evolved in animals: oviparity (egg laying)

and viviparity (live bearing).

Oviparous animals lay eggs in the environment, and their embryos develop outside the mother's body. Oviparous terrestrial animals such as insects and reptiles—including birds—protect their eggs from desiccation with waterproof membranes or shells. Oviparity is possible because eggs are stocked with abundant nutrients to supply the needs of the embryo. Some oviparous animals engage in various forms of parental behavior to protect their eggs, but until the eggs hatch, the embryos depend entirely on the nutrients stored in the egg.

Viviparous animals retain the embryo within the mother's body during its early developmental stages. The embryo is nourished and its wastes removed through exchanges with the mother's tissues. Viviparity occurs in many vertebrate groups, but with the exception of the prototherians (the monotremes), viviparity is universal in mammals. Therian mammals have a specialized portion of the female reproductive tract, the **uterus** or womb that contains the embryo until it is born. The early embryo arriving in the uterus from the Fallopian tube implants into the lining of the uterus. Implantation involves interactions between the tissues of the embryo and the uterus to form a **placenta**. Intimate contact in the placenta between the blood of the embryo and the blood of the mother facilitates the exchange of nutrients and wastes.

uterus (yoo' ter us) [L. *utero*: womb] A specialized portion of the female reproductive tract in mammals that receives the fertilized egg and nurtures the embryo in its early development. Also called the womb.

placenta (pla sen' ta) The organ in female mammals that provides for the nourishment of the fetus and elimination of the fetal waste products.

In most non-mammalian viviparous animals, such as garter snakes and the well-known aquarium fish the guppy, fertilized eggs are retained in the mother's body until they hatch. These embryos still receive nutrition from stores in the egg, so this reproductive adaptation is called **ovoviviparity**.

ovoviviparity Pertaining to reproduction in which fertilized eggs develop and hatch within the mother's body but are not attached to the mother by means of a placenta.

42.2 recap

Sexual reproduction involves gametogenesis, mating, and fertilization. Fertilization can be external or internal and involves mechanisms for ensuring that only one sperm from the right species enters the egg. Oviparous female animals lay eggs in the environment, and their embryos develop outside the mother's body. Viviparous female animals retain the developing embryo in the uterus until it is born.

learning outcomes

You should be able to:

- Explain the connection between sex chromosome asymmetry and spermatocytes remaining in cytoplasmic contact.
- Compare oogenesis and spermatogenesis.
- Summarize the interactions between sperm and eggs in sea urchins.

- Summarize ways aquatic animals enhance the likelihood that sperm and eggs of the same species will meet.
 - Identify and describe conditions that favor the evolution of hermaphroditism.
-

1. Crossing over is the reciprocal exchange of segments in homologous chromatids. Why does it occur more frequently in human oocytes than in human spermatocytes?
 2. If a mutation in a mammal eliminated the maintenance of cytoplasmic bridges between spermatids, would you expect all offspring sired by that mammal to be male or female? Explain your answer.
 3. In animals that spawn, what mechanisms ensure that an egg is fertilized by sperm of the same species, and by only one sperm?
 4. What are three situations in which hermaphroditism would be advantageous?
-

Now that we have covered some of the general aspects of gametogenesis and fertilization and have briefly discussed the great diversity of mating systems, we will next consider the human reproductive systems in detail.

42.3 Male Sex Organs Produce and May Deliver Sperm

This section describes the structures and functions of the male reproductive system in mammals, using humans as the prime example. You will also learn about the hormonal regulation of the male reproductive system. The discussion covers:

The primary sex organs, testes, that produce sperm and serve endocrine functions.

The accessory sex organs, including the ducts through which the sperm pass, the glands that produce and deliver secretions into those ducts, and the external genitalia.

Secondary sexual characteristics that result in male appearance but are not directly involved in reproduction.

focus your learning

Semen contains sperm and a mixture of molecules that support the sperm and facilitate fertilization.

Sexual stimulation triggers responses in the nervous system and penile arterioles that result in erection.

Spermatogenesis and the maintenance of male secondary sexual characteristics depend on testosterone.

Semen is the product of the male reproductive system

Semen contains sperm and a complex mixture of fluids and molecules (seminal fluid) that support the sperm and facilitate fertilization. Sperm make up less than 5 percent of the volume of the semen. Sperm are produced in the testes, the paired male gonads, and the seminal fluid is produced by accessory glands.

semen (see' men) [L. *semin*: seed] The thick, whitish liquid produced by the male reproductive system in mammals, containing the sperm.

Figure 42.9 illustrates the human male reproductive organs. The testes of most mammals are located outside the body cavity in a pouch of skin called the **scrotum**. Why should the testes be located outside the body cavity? The optimal temperature for spermatogenesis in most mammals is slightly lower than the normal body temperature. The scrotum keeps the testes at this optimal temperature. Muscles in the scrotum contract in a cold environment, bringing the testes closer to the warmth of the body; in a hot environment the muscles relax, cooling the testes by suspending them farther from the body.

(A) Posterior view

4 Seminal fluids are produced by the **seminal vesicles, prostate gland, and bulbourethral glands.**

3 Sperm are delivered to the urethra by the vas deferens which joins the seminal vesicle duct in the prostate gland to form the ejaculatory duct.

2 Sperm are stored and mature in the **epididymis.**

1 Sperm are produced in the **testes.**

5 Semen is ejaculated through the male copulatory organ, the **penis.**

(B) Side view

Q: What problem might an enlarged prostate gland produce?

Activity 42.1 **The Human Male Reproductive Tract** www.Life11e.com/ac42.1

scrotum In most mammals, a pouch outside the body cavity that contains the testes.

Spermatogenesis takes place within the [seminiferous tubules](#) tightly coiled in each testis (**Figure 42.10A**). Between the seminiferous tubules are clusters of [Leydig cells](#) that produce testosterone (**Figure 42.10B**). Spermatogonia reside in the outer regions of the seminiferous tubules, just under the basement membrane. Moving inward toward the lumen of the tubule are germ cells in successive stages of spermatogenesis (**Figure 42.10C**). The germ cells are intimately associated with [Sertoli cells](#) that provide nutrients for the developing sperm and secrete several things including hormones and growth factors that are necessary for spermatogenesis (which is why Sertoli cells are sometimes called “nurse cells”). Tight junctions (see [Key Concept 6.2](#)) between Sertoli cells create a blood-sperm barrier that prevents many harmful substances that can be circulating in the blood from getting to the developing sperm.

seminiferous tubules The tubules within the testes within which sperm production occurs.

Leydig cells The cells between the seminiferous tubules of the testes that secrete testosterone.

Sertoli cells Cells in the seminiferous tubules of the testes that nurture the developing sperm.

Figure 42.10 Spermatogenesis Takes Place in the Seminiferous Tubules (A) Seminiferous tubules fill the testes, continuously producing millions of sperm. **(B)** Cross section of seminiferous tubules and the Leydig cells in the spaces between them. **(C)** This longitudinal diagram shows how, as sperm mature, they move from the outer layer of the tubule toward the center, where they are shed into the lumen of the tubule.

 Activity 42.2 Spermatogenesis www.Life11e.com/ac42.2

When the second meiotic division is complete, each primary spermatocyte has produced four spermatids (see [Figure 42.4A](#)). The spermatids develop into spermatozoa as they migrate toward the lumen of the seminiferous tubule. The nucleus becomes compact, and the surrounding cytoplasm is lost. A flagellum—the sperm tail—develops. The mitochondria that provide the energy for sperm motility become condensed into a midpiece between the head and tail. An acrosome forms over the nucleus in the head of the sperm. Immature sperm are shed into the lumen of the seminiferous tubule.

From the seminiferous tubules, sperm move into the [epididymis](#) (see [Figure 42.9A](#)), where

they mature, become motile, and are stored. The epididymis connects to the [urethra](#) via the [vas deferens](#) (plural **vasa deferentia**) and the [ejaculatory duct](#). The urethra originates in the bladder, runs through the penis, and opens to the outside of the body at the tip of the penis. It serves as the common final duct for urine and semen.

epididymis (epuh did' uh mus) [Gk. *epi*: over + *didymos*: testicle] Coiled tubules in the testes that store sperm and conduct sperm from the seminiferous tubules to the vas deferens.

urethra (you ree' thra) In most mammals, the canal through which urine is discharged from the bladder and which serves as the genital duct in males.

vas deferens (plural: vasa deferentia) Duct that transfers sperm from the epididymis to the urethra.

ejaculatory duct The duct that carries semen from the seminal vesicle to the urethra.

The components of the semen other than sperm come from three accessory glands. About 60 percent of the volume of semen is secreted by the paired [seminal vesicles](#) that empty into the vas deferens just before it joins the urethra. Seminal fluid is thick because it contains mucus and fibrinogen, a protein also found in the blood, where it can polymerize to form blood clots. Seminal fluid also contains the monosaccharide fructose, an energy source for the sperm.

seminal vesicles Male accessory sex glands that contribute most of the volume of the semen including mucus, fibrinogen, and fructose.

The [prostate gland](#) contributes about 30 percent of the volume of the semen. Prostate fluid is alkaline, so it neutralizes the acidity in the male and female reproductive tracts and makes these environments more hospitable to sperm. The prostate also secretes a clotting enzyme that causes fibrinogen from the seminal vesicles to convert the semen into a clotted, gelatinous mass, facilitating the semen's propulsion into the upper regions of the female reproductive tract. Another prostate enzyme, fibrinolysin, then dissolves the clotted semen and liberates the sperm. Prostaglandins—hormones produced by the prostate—stimulate contractions of the female reproductive tract.

prostate gland In male humans, surrounds the urethra at its junction with the vas deferens; supplies an acid-neutralizing fluid to the semen.

The [bulbourethral glands](#) produce a small volume of an alkaline, mucoid secretion that helps neutralize acidity in the urethra and lubricate it to facilitate the passage of semen during the climax of sexual intercourse.

bulbourethral glands Secretory structures of the human male reproductive system that produce a small volume of an alkaline, mucoid secretion that helps neutralize acidity in the urethra and lubricate it to facilitate the passage of semen.

The penis and the scrotum are the male external genitalia

The shaft of the penis is covered with normal skin, but the highly sensitive tip, the [glans penis](#), is covered with thinner, more sensitive skin that is especially responsive to sexual stimulation. A

fold of skin called the foreskin covers the glans of the human penis. The procedure known as circumcision removes a portion of the foreskin.

glans penis The highly sensitive tip of the mammalian penis.

Sexual stimulation triggers responses in the nervous system that result in penile **erection**. Nerve endings release a neurotransmitter that causes the endothelial cells lining the penile blood vessels to release a gaseous neurotransmitter, nitric oxide (NO). NO diffuses into the smooth muscle cells that control the diameter of the penile arteries and stimulates them to produce the second messenger cGMP (see **Figure 7.13**). Increased cGMP in these muscle cells causes them to relax; the arteries dilate and carry more blood into the penis. Increased blood flow swells the shafts of spongy erectile tissue located along the length of the penis (see **Figure 42.9**). The enlargement of these blood-filled cavities compresses the vessels that carry blood out of the penis, and the erectile tissue becomes engorged with blood. The penis becomes hard and erect, facilitating its insertion into the vagina. Many species of mammals (though not humans) have a bone in the penis, but these species still depend on erectile tissue for copulation.

erection The state of the penis in which it is stiffened by engorgement with blood.

At the climax of copulation, 2 to 6 milliliters of semen are propelled through the vasa deferentia and the urethra in two steps, emission and ejaculation. During emission, rhythmic contractions of smooth muscles in the vasa deferentia and accessory glands move the semen into the urethra at the base of the penis. Ejaculation is caused by contractions of other muscles at the base of the penis surrounding the urethra. These contractions force the coagulum of semen through the urethra and out of the penis. The muscle contractions of ejaculation are accompanied by feelings of intense pleasure known as orgasm. They are also accompanied by transient increases in heart rate, blood pressure, breathing, pupil dilation, and skeletal muscle contractions throughout the body.

After ejaculation, NO release decreases and enzymes break down cGMP, causing the blood vessels flowing into the penis to constrict. The blood pressure in the erectile tissue decreases, relieving the compression of the blood vessels leaving the penis, and the erection declines.

Erectile dysfunction (ED), or impotence, is the inability to achieve or sustain an erection. ED may have different causes, including cardiovascular disease. Drugs used to treat ED act by inhibiting the enzyme that breaks down cGMP, thus enhancing the effect of NO released in the penis, which improves the ability to achieve and maintain an erection.

Male sexual function is controlled by hormones

Spermatogenesis and maintenance of male secondary sexual characteristics such as facial hair and a deep voice depend on testosterone produced by the Leydig cells of the testes. As described in **key concept 40.3**, increased production of testosterone at puberty results from an increased release of gonadotropin-releasing hormone (GnRH) by the hypothalamus. GnRH stimulates anterior pituitary cells to secrete luteinizing hormone (LH) and follicle-stimulating hormone (FSH) (**Figure 42.11**). Higher levels of LH stimulate the Leydig cells to increase their production and release of testosterone. Testosterone exerts negative feedback on the anterior pituitary and the hypothalamus. At the time of puberty, the sensitivity of the hypothalamus to negative feedback from testosterone declines; as a result, the level of circulating testosterone increases.

Figure 42.11 Male Reproductive Hormones The male reproductive system is under hormonal control by the hypothalamus and the anterior pituitary. Red lines indicate inhibition; green lines indicate stimulation and secretion.

Increased testosterone in pubertal boys causes the development of pubic and facial hair, a deeper voice, enlarged genitals, and an increased growth rate. Testosterone also promotes increased muscle mass and maturation of the testes. Continued production of testosterone after puberty is essential for the maintenance of secondary sexual characteristics and the production of sperm.

Spermatogenesis is controlled by the influence of FSH and testosterone on the Sertoli cells in the seminiferous tubules. The Sertoli cells also produce a hormone called inhibin that exerts negative feedback on the anterior pituitary cells producing and secreting FSH.

42.3 recap

Sperm are produced in the testes and are suspended in the seminal fluids produced by accessory glands. The resulting semen is ejaculated into the female reproductive tract during copulation. Prior to copulation, sexual stimulation causes the penis to become erect by increasing the blood flow into the erectile tissues. The male reproductive system is under hormonal control by the hypothalamus and anterior pituitary, with negative feedback coming from hormones produced by the testes.

learning outcomes

You should be able to:

- Summarize where the different components of semen are produced, and describe their functions.
 - Describe the anatomical and functional relationships between Leydig cells and Sertoli cells.
 - Describe the roles of NO and cGMP in the male sexual response.
 - Summarize the hormonal changes that occur during puberty in males and how they lead to the development of male secondary sexual characteristics.
-

1. What makes ejaculated semen thick and gelatinous, and how do sperm escape the gel to move up the female reproductive tract?
2. What are the roles of Sertoli cells in spermatogenesis?
3. cGMP is broken down by an enzyme called a phospho-diesterase. How does an inhibitor of that enzyme treat erectile dysfunction?
4. What is the significance of the fact that the testes of a prepubertal male are responsive to FSH and LH?

Whereas the male reproductive system produces sperm continuously throughout reproductive life, the female system produces eggs that can be fertilized by sperm periodically. We now turn to the cyclical processes by which the female reproductive system produces and releases eggs and prepares the female reproductive tract to receive a developing embryo should fertilization occur.

42.4 Female Sex Organs Produce Eggs and Nurture Embryos

Figure 42.12 illustrates the human female reproductive system. Eggs are produced in and released from the ovaries located on each side of the lower abdominal cavity. When an egg leaves the ovary (**ovulation**), it enters the abdominal cavity, but it does not go far. The ovaries are close to the openings of the **oviducts** (also known as the Fallopian tubes). The openings are surrounded by undulating, fringed tissues called fimbria that sweep the egg into the oviduct. Cilia lining the oviduct propel the egg toward the **uterus**, a muscular, thick-walled cavity shaped in humans like an upside-down pear. The uterus is where the embryo will develop if the egg is fertilized. At its bottom, the uterus narrows into a region called the **cervix**, which opens into the vagina.

(A) Front view

(B) Side view

Figure 42.12 Reproductive Tract of the Human Female The female reproductive organs are shown **(A)** from the front and **(B)** from the side.

ovulation Release of an egg from an ovary.

oviduct In mammals, the tube serving to transport eggs to the uterus or to the outside of the body.

uterus (yoo' ter us) [L. *utero*: womb] A specialized portion of the female reproductive tract in mammals that receives the fertilized egg and nurtures the embryo in its early development. Also called the womb.

cervix (sir' vix) [L. neck] The opening of the uterus into the vagina.

focus your learning

The menstrual (uterine) cycle refers to the buildup and breakdown of the endometrial lining of the uterus.

If pregnancy occurs, human chorionic gonadotropin (hCG) stimulates the corpus luteum to continue producing estrogen and progesterone.

Mechanical and hormonal stimuli are involved in labor.

The ovarian and uterine cycles are coordinated and timed by the same hormones that initiate sexual maturation.

Externally, the vagina is enclosed by two sets of skin folds. The inner, more delicate folds are the labia minora; the outer, thicker folds are the labia majora. At the anterior tip of the labia minora is the clitoris, a small bulb of highly sensitive erectile tissue that has the same developmental origins as the male glans penis. Clitoral tissues, homologous to the erectile tissues of the penis extend deep under the labia minora and the walls of the vagina. The labia minora and the clitoral tissues become engorged with blood in response to sexual stimulation. Just as stimulation of the glans penis during sexual intercourse culminates in orgasm in the male, stimulation of the clitoral tissues results in orgasm in the female.

The external opening of an infant's vagina is usually, but not always, partly covered by a thin membrane, the hymen. Eventually the hymen can be torn by vigorous physical activity or by first sexual intercourse; it can sometimes make first intercourse difficult or painful for the woman.

Sperm deposited in the vagina swim and are propelled by contractions of the female reproductive tract through the cervical opening, across the uterus, and most of the way up an oviduct, where fertilization takes place. Before meeting a sperm, the egg is still a secondary oocyte. Fertilization stimulates the egg to complete its second meiotic division. Following that division, the haploid nuclei of the sperm and the egg can fuse to produce a diploid zygote nucleus.

The ***zygote** undergoes its first few cell divisions to become a **blastocyst** while still in the oviduct. The blastocyst moves down the oviduct to the uterus, where it attaches itself to the epithelial lining of the uterus—the **endometrium**. Once attached, the blastocyst implants in the endometrium and interacts with it to form the placenta, as you will see in [Chapter 42](#). The mother's body nurtures the embryo through the placenta, which also produces hormones that sustain pregnancy.

blastocyst (blass' toe cist) An early embryo formed by the first divisions of the fertilized egg (zygote). In mammals, a hollow ball of cells.

endometrium The epithelial lining of the uterus.

The maturation of eggs and ovulation are cyclical events in the ovaries. Changes in the uterus are also critical processes. These cycles in humans average about 28 days, but they can vary considerably in an individual and among different individuals. In anticipation of receiving a blastocyst, the endometrium thickens and develops lots of blood vessels. The endometrium regresses if a blastocyst does not arrive within a certain window of time. Thus female reproductive functions consist of two linked cycles: an **ovarian cycle** that produces eggs and hormones; and a **uterine**, or **menstrual**, cycle that prepares the endometrium for the arrival of a blastocyst (**Focus: Key Figure 42.13**). The two cycles must be synchronized so that a blastocyst arrives in the uterus at the optimal time to implant in the endometrium and continue its development.

ovarian cycle (oh var' ee un) In human females, the monthly cycle of events by which eggs and hormones are produced. (Contrast with uterine cycle).

focus: key figure

(A) Changes in the ovary during the ovarian cycle

(B) Coordinated events in ovarian and uterine cycles

(C) Hormones control the ovarian and uterine cycles

Figure 42.13 The Ovarian and Uterine Cycles (A) The ovarian cycle progresses from the development of a follicle to ovulation and then to growth and finally to degeneration of the corpus luteum. (B) During a woman's ovarian and uterine cycles, coordinated changes occur in the development of the ovarian follicle, the release of female sex steroids, and the endometrial lining of the uterus. The release of hypothalamic GnRH stimulates the release of pituitary LH and FSH which in turn control the development of the follicle and eventually ovulation. The cycles begin with the onset of menstruation; ovulation is at midcycle (yellow bar). (C) The ovarian and uterine cycles are under a complex series of positive and negative feedback controls involving several hormones.

Q: Hormonal contraceptive pills contain estrogen and progesterone, which portion of the ovarian cycle do they simulate and how do they prevent ovulation?

Ovarian cycles produce mature eggs

A newborn baby girl has about a million primary oocytes in each ovary. By the time she reaches puberty, she has only about 200,000; the rest have degenerated. During a woman's fertile years, her ovaries go through about 450 ovarian cycles. During each cycle, 10 to 20 primary oocytes begin to mature, but usually only one matures completely and is ovulated; the others degenerate (see [Figure 42.13A](#)). At around the age of 50, a woman reaches **menopause**—the end of fertility—and may have few oocytes left in each ovary. For more than 50 years, the gradual age-related decline in oocytes was taken as evidence that oogenesis in humans is limited to prenatal life. However, in recent years oogonial stem cells (OSCs) have been isolated from adult ovaries of mice and of humans. These OSCs have been shown to be capable of division and production of oocytes. Thus menopause may not be the absolute end of fertility.

menopause In human females, the end of fertility and menstrual cycling.

A primary oocyte surrounded by a layer of ovarian cells is the functional unit of the ovary—the **follicle** (see the photo in [Figure 42.13A](#)). The follicle cells surrounding the oocyte supply it with nutrients and growth factors. The follicle cells are also the main site of production of the female hormones estrogen and progesterone. Usually only one follicle matures completely and reaches the stage of ovulation, releasing its egg at midcycle. Events that lead up to and follow ovulation are illustrated in [Figure 42.13B](#). Follicle maturation occurs in the first half of the cycle, therefore called the follicular phase. The midcycle point at which the follicle ruptures to release the oocyte is marked by a vertical yellow bar. The notable hormonal event leading up to ovulation is the gradual and then escalating increase in estrogen, which peaks just prior to midcycle (see [Figure 42.13B](#)).

follicle [L. *folliculus*: little bag] In female mammals, an immature egg surrounded by nutritive cells.

The second half of the ovarian cycle is called the luteal phase because the follicle cells left in the ovary after the egg is ovulated develop into an endocrine gland—the **corpus luteum** (yellow body)—secreting estrogen and progesterone. If the egg is not fertilized and does not embed into the endometrium, the corpus luteum becomes inactive and degenerates in 12 to 14 days.

corpus luteum (kor' pus loo' tee um) (plural: corpora lutea) [L. yellow body] A structure formed from a follicle after ovulation; produces hormones important to the maintenance of pregnancy.

The uterine cycle prepares an environment for a fertilized egg

The uterine cycle parallels the ovarian cycle and consists of a buildup and then a breakdown of the endometrium (see [Figure 42.13B](#)). The breakdown of the endometrium, or **menstruation** (Latin *menses*, “months”), marks the beginning of each uterine and ovarian cycle. About 5 days

after menstruation begins, the endometrium starts to thicken in preparation for receiving a blastocyst. The uterus attains its maximal state of preparedness about 5 days after ovulation and remains in that state for another 9 days. If a blastocyst has not arrived by that time, the endometrium breaks down and the sloughed-off tissue, including blood, flows from the body through the vagina as a menstrual discharge.

menstruation The process by which the endometrium breaks down, and the sloughed-off tissue, including blood, flows from the body.

The uterine cycles of most mammals other than humans do not include menstruation; instead, the uterine lining typically is reabsorbed. In these species, the most obvious correlate of the ovarian cycle is a state of sexual receptivity called **estrus** (“heat”) around the time of ovulation. You may be aware of the bloody discharge that occurs in dogs at the time of estrus. This discharge is not the same as menstruation — in fact it is exactly the opposite. Bleeding in dogs occurs during the *proliferation* of the uterine lining, which occurs just before ovulation. When the female mammal comes into estrus, she actively solicits male attention and may be aggressive to other females. Humans are unusual among mammals in that females are potentially sexually receptive throughout their ovarian cycles and at all seasons of the year.

estrus (es’ trus) [L. *oestrus*: frenzy] The period of heat, or maximum sexual receptivity, in some female mammals. Ordinarily, estrus is also the time of release of eggs in the female.

Hormones control and coordinate the ovarian and uterine cycles

The ovarian and uterine cycles are coordinated and timed by the same hormones that initiate sexual maturation. Gonadotropins (FSH and LH) secreted by the anterior pituitary are the central elements of this control (see [Figure 42.13B](#)). Before puberty (i.e., before about 11 years of age), the secretion of FSH and LH is low and the ovaries are inactive. At puberty the hypothalamus increases its release of GnRH, stimulating the anterior pituitary to secrete FSH and LH. In response to FSH and LH, ovarian tissue grows and produces estrogen. The rise in estrogen causes the maturation of the accessory sex organs and the development of female secondary sexual characteristics. Between puberty and menopause, interactions of GnRH, gonadotropins, and sex steroids control the ovarian and uterine cycles.

A few days before menstruation begins, the anterior pituitary begins to increase its secretion of FSH and LH. In response, several follicles begin to mature in the ovaries, and these follicles steadily increase their production of estrogen. After about a week, all but one of the follicles wither away.

For the first 12 days of a 28-day ovarian cycle, estrogen exerts positive rather than negative feedback control on the pituitary. As a result, a surge of LH and a lesser surge of FSH occur (see [Figure 42.13B](#)). The LH surge triggers the mature follicle to rupture and release its egg, and it stimulates the cells of the ruptured follicle to develop into a corpus luteum.

Estrogen and progesterone secreted by the corpus luteum following ovulation are crucial to growth and maintenance of the endometrium. These sex steroids also exert negative feedback control on the pituitary, inhibiting gonadotropin release and thus preventing new follicles from maturing.

If the egg is not fertilized, the corpus luteum degenerates on about day 26 of the cycle. Without production of progesterone by the corpus luteum, the endometrium sloughs off and menstruation occurs. The decrease in circulating steroids also releases the hypothalamus and pituitary from negative feedback control, so GnRH, FSH, and LH all begin to increase. The increase in these hormones induces the next round of follicle development, and the ovarian

cycle begins again.

FSH receptors determine which follicle ovulates

Early in the ovarian cycle several follicles begin to develop, but only one reaches full maturity. What determines which one will survive? There are two types of follicle cells, arranged in two layers. The inner layer immediately surrounding the ovum is made up of **granulosa cells**, and the outer layer consists of **thecal cells**. Thecal cells are stimulated by LH to produce testosterone (similar to Leydig cells in the male). Testosterone diffuses into the granulosa cells, where the enzyme aromatase converts the testosterone to estrogen. Estrogen, along with FSH, stimulates the growth and maturation of the granulosa cells (similar to the Sertoli cells in the male). The estrogen plays two important roles in the selection of the follicle that will ovulate: (1) estrogen stimulates the granulosa cells to express more FSH and LH receptors, and (2) estrogen entering the circulation feeds back on the pituitary to decrease the production of FSH. The granulosa cells also produce inhibin (similar to Sertoli cells in the male), and inhibin also decreases the production of FSH. As FSH and LH levels fall, the follicle with the most FSH and LH receptors survives and matures while the others regress.

In pregnancy, hormones from the extraembryonic membranes take over

If the egg is fertilized and a blastocyst arrives in the uterus and implants in the endometrium, a new hormone comes into play. A layer of cells covering the blastocyst begins to secrete **human chorionic gonadotropin**, or **hCG** (**Figure 42.14**). This gonadotropin, a molecule similar to LH, stimulates the corpus luteum to continue to produce estrogen and progesterone to support the growth and maintenance of the endometrium and thereby prevent menstruation. Because it is present only in the blood of pregnant women, the presence of hCG is the basis for pregnancy testing. Pregnancy tests use an antibody to detect hCG in urine; they take only minutes and can be done at home.

human chorionic gonadotropin (hCG) A hormone secreted by the placenta that sustains the corpus luteum and helps maintain pregnancy.

hCG See human chorionic gonadotropin.

Figure 42.14 Pregnancy and Childbirth When a fertilized ovum implants in the uterus, cells surrounding it produce human chorionic gonadotropin, which acts like LH and keeps the corpus luteum functioning as an endocrine gland. The ovarian and uterine cycles are put on hold for the duration of pregnancy.

Blastocyst and endometrial tissues form the placenta, which nourishes the embryo. The placenta also replaces the corpus luteum as the major producer of estrogen and progesterone. Continued high levels of estrogen and progesterone prevent the pituitary from secreting gonadotropins; thus the ovarian cycle ceases for the duration of pregnancy. This mechanism underlies the action of birth control pills, which contain synthetic hormones resembling estrogen and progesterone that exert negative feedback control on the hypothalamus and pituitary.

Breast feeding delays the return of the ovarian cycle

Following birth, estrogen and progesterone levels drop because of the loss of the placenta, and therefore negative feedback on the hypothalamus and pituitary imposed by these hormones during pregnancy is gone. Nevertheless, women who breast feed their infants may not have their ovarian and menstrual cycles return for some time—a phenomenon called lactational delay. In [Figure 40.4](#) you learned that the pituitary hormone prolactin stimulates the growth of the mammary glands and the production of milk. Prolactin release is stimulated by the suckling of the infant. Even the sight or sound of the infant can stimulate prolactin release in the mother. Investigations have now shown that in addition to stimulating the mammary glands, prolactin also inhibits GnRH release and LH release, possibly explaining lactational delay. Going back to the case of the tammar wallaby in the opening to this chapter, could prolactin release stimulated by the suckling of the joey in the pouch be responsible for the delayed implantation seen in this species? **Investigating Life: The Control of Diapause in the Tammar Wallaby** examines this question.

Childbirth is triggered by hormonal and mechanical stimuli

Throughout pregnancy, the muscles of the uterine wall periodically undergo slow, weak, rhythmic contractions called Braxton Hicks contractions. These contractions become stronger during the third trimester of pregnancy and are sometimes called false labor. The contractions of true labor mark the beginning of childbirth. Both hormonal and mechanical stimuli contribute to the onset of labor ([Figure 42.15A](#)).

Progesterone inhibits and estrogen stimulates contractions of uterine muscle. Toward the end of the third trimester, the estrogen- progesterone ratio shifts in favor of estrogen. The onset of labor is marked by increased secretion of the hormone oxytocin by the posterior pituitaries of both mother and fetus. Oxytocin is a powerful stimulant of uterine muscle contraction. Manufactured oxytocin is used to induce labor when that is necessary.

Mechanical stimuli come from the stretching of the uterus by the fully grown fetus and the pressure of the fetal head on the cervix. These mechanical stimuli increase the release of oxytocin by the mother's posterior pituitary, which in turn increases the activity of uterine muscle, causing even more pressure on the cervix. This positive feedback loop converts the weak, slow, rhythmic Braxton Hicks contractions into stronger labor contractions.

In the early stage of labor, hormonal changes and pressure created by the contractions cause the cervix to dilate (expand) until it is large enough to allow the baby to pass through. Gradually the contractions become more frequent and more intense. This stage of labor lasts an average of 12 to 15 hours in a first pregnancy, but is usually 8 hours or less in subsequent ones.

The second stage of labor begins when the cervix is fully dilated to a diameter of about 10 cm ([Figure 42.15B](#)). The baby's head can now move into the vagina. Passage of the fetus through the vagina is assisted by the mother's bearing down ("pushing") with her abdominal and other muscles. Once the head and shoulders of the baby clear the cervix, the rest of its body eases out rapidly, but it is still connected to the placenta by the umbilical cord. Once the baby clears the birth canal, it starts breathing and is independent of its mother's circulation. The umbilical cord may then be clamped and cut. The segment still attached to the baby dries up and sloughs off in a few days, leaving behind its distinctive signature, the belly button—more properly called the umbilicus. The third stage of labor, the detachment and expulsion of the placenta and fetal membranes, takes from a few minutes to an hour, and may be accompanied by uterine

contractions. A baby's suckling at the breast immediately following birth stimulates additional secretion of oxytocin, which augments uterine contractions, reduces the size of the uterus, and helps stop bleeding.

Figure 42.15 Labor and Delivery (A) Both mechanical and hormonal signals are involved in stimulating the uterine contractions of labor and delivery. **(B)** A new person comes into the world headfirst.

the Tammar Wallaby

experiment

Original Paper: Hinds, L. A. and C. H. Tyndale-Biscoe. 2013. Daily prolactin pulse inhibits the corpus luteum during lactational quiescence in the marsupial, *Macropus eugenii*. *Reproduction, Fertility, and Development* 25: 456–461.

In Chapter 40 (see Figure 40.4) we discussed how the hormone prolactin (PRL) has evolved to serve many physiological processes in different vertebrate groups, but these various processes all have some connection to reproduction. Since prolactin is involved in controlling lactation in mammals, could prolactin be the signal in the tammar wallaby that maintains embryonic diapause as long as suckling continues?

HYPOTHESIS ▶ Pulses of prolactin in lactating female tammar wallabies prevent new embryos from developing as long as previous offspring are suckling.

METHOD

The hormone progesterone (P) prepares the uterine lining for implantation of an embryo and maintains the uterine lining during pregnancy. Thus measurements of blood levels of P reveal when diapause is broken in tammar wallabies. A stimulus known to break diapause in these animals is the removal of the prior young from the pouch (RYP). The RYP method was used to study the effects of prolactin on maintenance of diapause.

1. Remove young from the pouches of three groups of five wallabies.
2. Following RYP administer the following treatments:
 - Group A: saline injection for 8 days following RYP (controls)
 - Group B: PRL injection every 24 hr for 8 days following RYP
 - Group C: PRL injection every 48 hr for 8 days following RYP
3. Take daily blood samples to measure P levels.

RESULTS

Data are approximate means of the actual measurements, progesterone concentrations (P) expressed in picograms per milliliter (pg/mL).

Days following RYP	P level (picograms/mL)		
	Group A	Group B	Group C
0	100	125	100
1	150	175	113
2	150	125	125
3	180	150	135
4	300	150	175
5	450	125	215
6	175	125	240
7	200	150	325
8	175	16	210
9	175	175	240
10	225	250	335
11	200	450	260
12	250	350	200
13	225	225	225
14	300	250	230
15	350	200	210
16	360	225	225

CONCLUSION ▶ When tammar wallabies were treated with daily saline injections (controls), they broke diapause 4 to 5 days following RYP. However, when they were treated with daily PRL injections, they broke diapause 11 or 12 days following RYP. Hence daily PRL pulses can prolong diapause and delay implantation of a new blastocyst.

work with the data

Following the experiment showing that daily pulses of PRL can maintain diapause, the investigators asked whether pulses of PRL every 2 days could maintain diapause. The data are shown in the table as Group C. Plotting the data will show if there is a difference in the response to PRL when pulses were given every other day following RYP.

QUESTION

1. Plot the data as was done for Groups A and B. Was the 48-hr PRL pulse effective in preventing the breaking of diapause?

A similar **work with the data** exercise may be assigned in **LaunchPad**.

Birth as well as reproduction is timed

Reproduction in many species is seasonal. This seasonality in many species of vertebrates involves mechanisms of photoperiodism. Briefly, changes in day length enable animals to anticipate the best time of year for the rearing of young and therefore time their reproduction and birth accordingly. How do animals measure day length? As we will discuss in more detail in [Chapter 52](#), animals have endogenous daily rhythms called circadian (*circa*, “day,” + *dia*, “length”) rhythms. As day length changes, sunrise and sunset occur at different phases of the circadian rhythm. The release of melatonin from the pineal gland is controlled by the circadian rhythm but is inhibited by light. Therefore as days get longer, the nightly pulse of melatonin gets shorter, and conversely as days get shorter, the melatonin pulse gets longer. Day length determines when many species come into reproductive condition and mate. That is not true for

the tammar wallaby that was introduced at the beginning of this chapter. The wallaby mates at any time of year soon after it gives birth. However, diapause in the wallaby is sensitive to night length—that is, to the duration of the melatonin pulse. A non-lactating wallaby will break diapause when night length reaches 12 hr. Similarly, when non-lactating wallabies are held at a night length of 9 hr but given melatonin injections 2.5 hr before sunset, they break diapause. These results support the hypothesis that short daily melatonin pulses prolong diapause and that long daily melatonin pulses are a signal to break diapause. The significance for the nocturnal wallaby is that birth tends to be at the time of year when nights are longest.

Humans are not seasonal breeders, but there is a timing component of childbirth. Most women go into labor at night. However, it is quite common for labor to cease when women arrive in the brightly lit hospital. Bright light interrupts the nightly melatonin pulse in humans. The work with the data exercise (Circadian Timing, Hormone Release, and Labor) explores whether melatonin is involved in the timing of human births.

42.4 recap

The reproductive system of women produces oocytes (eggs) and hormones, and these functions are controlled by hypothalamic and anterior pituitary hormones. The follicle is the functional unit of the ovary. Usually one follicle matures and ovulates each month as controlled by a cyclical feedback interplay between ovarian hormones and the hypothalamic-pituitary axis. These hormonal cycles also coordinate the uterine, or menstrual, cycle so that the endometrium is prepared to receive a blastocyst should fertilization occur. A blastocyst implanted in the uterus produces hCG, which suspends the ovarian and uterine cycles by sustaining the ovarian production of progesterone and estrogen until the placenta can take over this function. Childbirth and lactation are controlled by mechanical and hormonal mechanisms.

learning outcomes

You should be able to:

- Link the events in the ovarian and menstrual cycles.
- Describe the interaction between the granulosa cells and the thecal cells of the follicle in limiting the number of eggs that are ovulated in each cycle.
- Explain how the blastocyst prevents menstruation.
- Explain how mechanical and hormonal stimuli interact during labor.

1. What events in the ovary are responsible for the onset of menses, and what prevents menses if pregnancy occurs?
2. What are the roles of thecal cells and granulosa cells in the ovarian cycle, and how do they limit the number of eggs that are ovulated?
3. How does positive feedback between hormonal and mechanical processes play a role in childbirth?

Understanding the physiology of human reproduction has led to numerous methods and technologies for controlling it, either to prevent unwanted pregnancies or to overcome infertility.

42.5 Fertility Can Be Controlled

Sexual issues and sexual behavior are dominant aspects of our society, and reproductive technologies have had huge impacts on our sexual and reproductive lives.

focus your learning

- Birth control techniques are designed to prevent fertilization and/or implantation.
- Assisted reproductive technologies enable couples who are infertile to have children.

Humans use a variety of methods to control fertility

According to a recent study, almost half of the more than 6 million pregnancies that occur in the United States each year are unintended. For women of college age, a single act of unprotected intercourse in the 2 days prior to ovulation carries a chance of conception as high as 50 percent. The only failure-proof methods of preventing pregnancy are either complete abstinence from sexual activity or surgical removal of the gonads. Those options are not acceptable to most people, and they turn to other methods to prevent pregnancy. Many of these methods prevent fertilization or implantation (conception) and are therefore referred to as **contraception**. [Table 42.1](#) lists some of the most commonly used contraceptive methods and their relative failure rates; note that these methods vary enormously in their effectiveness. Most methods are used by the woman, although some are used by the man.

table 42.1 Methods of Contraception			
Method	Mode of action	Failure rate ^a	Comments
Unprotected	No form of birth control.	85	High risk of pregnancy, especially for women 15-30.
Nontechnological methods			
Rhythm method	The couple abstains from intercourse between days 10 and 20 of the ovarian cycle (peak fertility).	15-35	High failure rate due to miscalculation and/or variation of individual cycles.
Coitus interruptus	The man withdraws his penis prior to ejaculation with the intention of not depositing sperm into the vagina.	20-40	Requires self-control, especially by the man. Very high failure rate.
Barrier methods ^b			
Condom (male or female)	A sheath of impermeable material (often latex) is fitted over the erect penis or into the vagina. Semen is trapped in the condom, so no sperm are deposited in the vagina.	3-20	If fitted correctly, an intact condom can prevent pregnancy. Failure can be due to material failure or improper use. Condoms are the only

			contraceptive method that protects against sexually transmitted diseases (STDs), including HIV (AIDS).
Spermicidal jellies	Applied deep inside the vagina, these chemical compounds kill or immobilize sperm.	25	Used alone, spermicidal compounds have a high failure rate.
Diaphragms, cervical caps, cervical sponges containing spermicide	Inserted by the woman prior to intercourse, these devices work by blocking the cervix so that sperm cannot pass into the uterus.	15-30	Approximately the same failure rate as condom use by men, but do not protect against STDs. Can be used in conjunction with spermicidal jelly for extra protection.
Hormone-based contraceptives			
Oral hormones ("the pill")	A daily pill for women containing a combination of synthetic estrogens and progesterone. These hormones mimic pregnancy to the extent that the ovarian cycle and ovulation are suspended. The uterine cycle can continue by including a week of non-hormone administration every 21-28 days.	0-3	Requires medical consultation and prescription. Taken correctly, oral contraceptives are extremely effective. In the United States, more than 12 million women use them each year; they are sometimes prescribed to treat menstrual disorders.
Non-orally administered hormones	Making use of same hormonal actions as the pill, these methods include long-acting injections, patches that release hormones transdermally (through the skin), and a hormone-containing vaginal ring. Implantable progestin releasing have a failure rate of <1 and can last up to 3 years.	<5	Same as oral hormones. A slightly lower failure rate because the woman does not have to remember to take a daily pill.
Progestin-only pill (Plan Bb)	An oral contraceptive meant to be taken within 72 hours after unprotected sex. A high dose of progestin in two pills prevents ovulation in the same manner birth control pills do.	5-40	Not an "abortion pill," this drug will not terminate an existing pregnancy. Currently available to women over 17 without a prescription. Failure rate varies widely depending on when taken.
Implantation blockers			
Intrauterine device (IUD)	A medical professional inserts a small plastic or metal device into the uterus. The resulting inflammation reaction (see Chapter 40) releases prostaglandins, which prevent	<1	A highly effective contraceptive, it is the most widely used birth control device in China (and hence the world).

implantation of the fertilized egg.

With medical monitoring, can remain in place for several years.

Contraception
pill

Mifepristone or RU-486 is a drug that blocks the action of progesterone that is necessary to maintain the endometrium during implantation and pregnancy.

0.5-6 Prevents implantation when taken up to several days after unprotected intercourse. Can terminate a pregnancy up to the time of the first missed menstrual period. In the United States, available from specialized providers.

Sterilization

Vasectomy

The vasa deferentia (see [Figure 42.9](#)) are cut and tied off so that sperm can no longer pass into the urethra. Sperm continue to be produced but are reabsorbed by the man's body. Male hormone levels and sexual responses are not affected.

0-0.15 A simple surgical procedure performed under local anesthetic in a doctor's office. Although theoretically it can be reversed, vasectomy should be considered permanent.

Tubal ligation

The oviducts (see [Figure 42.12A](#)) are tied off so that eggs cannot reach the uterus and sperm cannot reach the egg. As with vasectomy, hormone levels and sexual responses are not affected.

0-0.05 This surgical procedure is somewhat more complex than vasectomy. It is often performed in conjunction with childbirth when a woman has decided that her family is complete.

^aFailure rate refers to the number of pregnancies per 100 women per year.

^bAll of these barrier methods are routinely available without medical prescription.

contraception Birth control methods that prevent fertilization or implantation (conception).

Once a fertilized egg is successfully implanted in the uterus, any termination of the pregnancy is called an **abortion**. A spontaneous abortion is the medical term for what is commonly called a miscarriage. Spontaneous abortions frequently occur early in pregnancy and are usually the result of either a chromosomal abnormality in the fetus or a breakdown in the process of implantation. Many spontaneous abortions occur before the woman even realizes she is pregnant.

abortion Any termination of pregnancy, whether induced or natural (in which case it is called a spontaneous abortion), that occurs after a fertilized egg is successfully implanted in the uterus.

Abortions that result from medical intervention may be performed either for therapeutic purposes or for fertility control. A therapeutic abortion may be necessary to protect the health of the mother, or it may be performed because prenatal testing reveals that the fetus has a severe defect. In a medical abortion, the cervix is dilated and some of the endometrium, along with the implanted fetus, is removed. When performed in the first trimester of a pregnancy, a medical abortion carries less risk of death to the mother than a full-term pregnancy. The risk rises after the first 12 weeks of pregnancy but remains less than that of a full-term pregnancy through the second trimester.

Reproductive technologies help solve problems of infertility

About 15 percent of couples in the United States are infertile—that is, they can't have children. The reasons for infertility are many, and are about equally distributed between men and women. Several technologies have been developed to overcome barriers to both conceiving and bearing a child. The simplest of these is [artificial insemination](#), in which the physician places sperm in the woman's reproductive tract. This technique is useful if the male's sperm count is low, if his sperm lack motility, or if problems in the female's reproductive tract prevent the normal movement of sperm up the oviducts. Artificial insemination is also widely used in the production of domesticated animals such as cattle.

artificial insemination An infertility treatment that involves the artificial introduction of sperm into the woman's reproductive tract.

[Assisted reproductive technologies](#), or **ARTs**, involve procedures that remove unfertilized eggs from the ovary, combine them with sperm outside the body, and then place fertilized eggs or egg-sperm mixtures in the appropriate location in the woman's reproductive tract for development to take place. The first successful ART was in vitro fertilization (IVF). In IVF the woman is treated with hormones that stimulate many follicles in her ovaries to mature. Eggs are collected from these follicles, and sperm are collected from the intended father. Eggs and sperm are combined in a culture medium outside the body, where fertilization takes place. The resulting embryos can be injected into the mother's uterus in the blastocyst stage or kept frozen for implantation later. The first "test tube baby" resulting from IVF was born in England in 1978. Since then, millions of babies have resulted from this ART.

assisted reproductive technologies (ARTs) Any of several procedures that remove unfertilized eggs from the ovary, combine them with sperm outside the body, and then place fertilized eggs or egg-sperm mixtures in the appropriate location in a female's reproductive tract for development.

A major cause of IVF failure is failure of sperm to gain access to the egg cell membrane (see [Figure 42.5](#)). To solve this problem, methods have been developed to inject a sperm cell directly into the cytoplasm of an egg. In intracytoplasmic sperm injection (ICSI), an egg is held in place by suction applied through a polished glass pipette. A slender, sharp pipette is then used to penetrate the egg and inject a sperm ([Figure 42.16](#)). This ART was used successfully for the first time in 1992 by researchers in Belgium; now thousands of these procedures are performed in U.S. clinics each year, with a success rate of about 25 percent.

Figure 42.16 Intracytoplasmic Sperm Injection In this procedure, a sperm is injected directly into a mature egg cell. The fertilized egg is then placed in the female reproductive tract, where it can implant and develop into a fetus.

IVF, coupled with techniques of genetic analysis, can eliminate the risk that adults who are carriers of genetic diseases will produce affected children. It is now possible to take a cell from a human embryo at the 4- or 8-cell stage (see [Figure 43.3](#)) without damaging its developmental potential. The sampled cell can be subjected to molecular analysis to determine whether it carries the harmful gene. This procedure, called preimplantation genetic diagnosis (PGD), makes it possible to determine whether an embryo produced by IVF carries the genetic defect of concern.

42.5 recap

Controlling fertility is an important aspect of modern human life. Decreasing the probability of pregnancy is achieved through methods that prevent sperm and egg from meeting and from preventing implantation. Pregnancies can be facilitated through technologies that extract eggs from the ovary and fertilize them in vitro before reintroducing them into the female reproductive tract.

learning outcomes

You should be able to:

- Describe the relative advantages and disadvantages of different contraceptive methods.
- Compare contraception and contragestational techniques.
- Explain how procedures that use genetic analysis and in vitro fertilization (IVF) can help carriers of genetic disease avoid producing afflicted children.

1. Which method of contraception is the only one to offer protection against sexually transmitted diseases (STDs)? Explain your answer.
2. Both the contraceptive pill (“the pill”) and the contragestational pill (RU-486) involve progesterone signaling. How do their mechanisms of action differ?
3. How can IVF be used to prevent transmission of a genetic disease?

The fertilized egg of a sexually reproducing organism is a single cell containing all the genetic information needed to create a new organism. [Chapter 19](#) introduced some of the molecular aspects of the process of development in multicellular animals. [Chapter 43](#) will describe the physiological and anatomical events of animal development.

investigatinglife

What signal controls the breaking of diapause in the tammar wallaby?

The experiment presented in Investigating Life: The Control of Diapause in the Tammar Wallaby exploited the fact that removal of the young joey from the pouch of its mother (RYP) stimulated the blastocyst in her uterus to break diapause, implant, and continue development. What diapause-breaking signal might be involved in conjunction with RYP? Researchers hypothesized that RYP resulted in cessation of prolactin release stimulated by suckling of the young, and that the absence of those prolactin pulses initiated the breaking of diapause. The test of that hypothesis was to apply RYP to groups of mother wallabies and test whether applications of prolactin could prevent the breaking of diapause. The results showed that injections of prolactin every 24 hr for 8 days following RYP delayed the progesterone rise that indicates the breaking of diapause. Prolactin injections at 48-hr or longer intervals were less effective or ineffective in maintaining diapause. The conclusion was thus reached that prolactin pulses stimulated by suckling are a signal for the maintenance of diapause, and that the removal of that signal results in the breaking of diapause. Another signal, melatonin, could be involved in the breaking of diapause. The prolactin experiments were all done at the time of year when night length was appropriate for the breaking of diapause.

Future directions

Reproductive success depends on many factors, including ecological, physiological, and socio-behavioral factors. It is therefore not surprising that evolutionary adaptations have exploited many kinds of information to control the timing of reproduction in various species. While these controlling factors are diverse, in vertebrates they all work through the hypothalamic, pituitary, and gonadal regulatory mechanisms. Therefore whatever we can learn about the physiology of reproduction in one vertebrate species may also apply to other species, or at least inform us as to what questions we should ask of other species, including humans. The answers to these questions can help us preserve endangered species, improve domesticated species, solve reproductive problems in humans, and even help control human population growth.

▶ 42.1 Asexual Reproduction Is Efficient but Limits Genetic Variability

- Asexual reproduction produces offspring that are genetically identical to their parent and to one another; it produces no genetic diversity.
- Means of asexual reproduction include [budding](#), [regeneration](#), and [parthenogenesis](#).
Review Figures 42.1- 42.3

bud A protuberance on a stem that contains an undeveloped leaf, shoot, or flower.

regeneration The development of a complete individual from a fragment of an organism.

parthenogenesis [Gk. *parthenos*: virgin] Production of an organism from an unfertilized egg.

▶ 42.2 Sexual Reproduction Involves Union of Haploid Egg and Sperm

- Sexual reproduction involves three basic steps: [gametogenesis](#), [spawning](#) or [mating](#), and [fertilization](#).

gametogenesis (ga meet' oh jen' e sis) The specialized series of cellular divisions that leads to the production of gametes. Called oogenesis when referring to processes in the ovary and spermatogenesis in the testis.

spawning See external fertilization.

mating The joining of individuals for the purpose of reproduction.

fertilization Union of gametes. Also known as syngamy.

- Gametogenesis and fertilization are similar in all animals, but spawning and mating include a great variety of anatomical, physiological, and behavioral adaptations.
- Gametogenesis occurs in **testes** and **ovaries**. In spermatogenesis (the production of [sperm](#)) and oogenesis (the production of eggs), the [germ cells](#) proliferate mitotically, undergo meiosis, and mature into gametes.

sperm [Gk. *sperma*: seed] The male gamete.

germ cell [L. *germen*: to beget] A reproductive cell or gamete of a multicellular organism. (Contrast with somatic cell.)

- Each [primary spermatocyte](#) can produce four haploid sperm through the two divisions of meiosis. **Review Figure 42.4A**

primary spermatocyte The diploid progeny of a spermatogonium; undergoes the first meiotic division to form secondary spermatocytes.

- [Primary oocytes](#) immediately enter prophase of the first meiotic division, and in many

species, including humans, their development is arrested at this point. each [oogonium](#) produces only one egg. **Review Figure 42.4B**

primary oocyte (oh' eh site) [Gk. *oon*: egg + *kytos*: container] The diploid progeny of an oogonium. In many species, a primary oocyte enters prophase of the first meiotic division, then remains in developmental arrest for a long time before resuming meiosis to form a secondary oocyte and a polar body.

oogonium (oh' eh go' nee um) (plural: oogonia) (1) In some algae and fungi, a cell in which an egg is produced. (2) In animals, the diploid progeny of a germ cell in females.

- Fertilization involves sperm activation, species-specific binding of sperm to egg, the acrosomal reaction, digestion of a path through the protective coverings of the egg, and fusion of sperm and egg cell membranes. Fusion of these two membranes triggers [blocks to polyspermy](#), which prevent additional sperm from entering the egg and, in mammals, signal the egg to complete meiosis and begin development. **Review Figure 42.5, Animation 42.1**

block to polyspermy Any of several responses to entry of a sperm into an egg that prevent more than one sperm from entering the egg.

- [External fertilization](#) is common in aquatic species. [Internal fertilization](#) is necessary in terrestrial species and usually involves copulation.

external fertilization The release of gametes into the environment; typical of aquatic animals. Also called spawning. (Contrast with internal fertilization.)

internal fertilization The release of sperm into the female reproductive tract; typical of most terrestrial animals. (Contrast with external fertilization.)

- **Hermaphroditic**, or [monoecious](#), species have both male and female reproductive systems in the same individual, either sequentially or simultaneously. [Dioecious](#) species have separate male and female individuals.

monoecious (mo nee' shus) [Gk. *mono*: one + *oikos*: house] Pertaining to organisms in which both sexes are "housed" in a single individual that produces both eggs and sperm. (In some plants, these are found in different flowers within the same plant.) Examples include corn, peas, earthworms, hydras. (Contrast with dioecious.)

dioecious (die eesh' us) [Gk. *di*: two + *oikos*: house] Pertaining to organisms in which the two sexes are "housed" in two different individuals, so that eggs and sperm are not produced in the same individuals. Examples: humans, fruit flies, date palms. (Contrast with monoecious.)

- Animals can be classified as oviparous or viviparous, depending on whether the early stages of development occur outside or inside the mother's body.

► 42.3 Male Sex Organs Produce and May Deliver Sperm

- Males produce [semen](#) consisting of sperm suspended in seminal fluid (which nourishes the sperm and facilitates fertilization).

semen (see' men) [L. *semin*: seed] The thick, whitish liquid produced by the male reproductive system in mammals, containing the sperm.

- Sperm are generated in the [seminiferous tubules](#) of the testes, mature in the [epididymis](#), and are delivered to the [urethra](#) through the **vasa deferentia**. Other components of semen are produced in the [seminal vesicles](#), [prostate gland](#), and [bulbourethral glands](#). **Review Figure 42.9, Activities 42.1, 42.2**

seminiferous tubules The tubules within the testes within which sperm production occurs.

epididymis (epuh did' uh mus) [Gk. *epi*: over + *didymos*: testicle] Coiled tubules in the testes that store sperm and conduct sperm from the seminiferous tubules to the vas deferens.

urethra (you ree' thra) In most mammals, the canal through which urine is discharged from the bladder and which serves as the genital duct in males.

seminal vesicles Male accessory sex glands that contribute most of the volume of the semen including mucus, fibrinogen, and fructose.

prostate gland In male humans, surrounds the urethra at its junction with the vas deferens; supplies an acid-neutralizing fluid to the semen.

bulbourethral glands Secretory structures of the human male reproductive system that produce a small volume of an alkaline, mucoid secretion that helps neutralize acidity in the urethra and lubricate it to facilitate the passage of semen.

- All components of the semen join in the urethra at the base of the [penis](#) and are ejaculated through the erect penis by muscle contractions at the climax of copulation.

penis An accessory sex organ of male animals that enables the male to deposit sperm in the female's reproductive tract.

- Spermatogenesis depends on testosterone secreted by the [Leydig cells](#) of the testes, which are under the control of hormones produced in the anterior pituitary and the hypothalamus. The production of these hormones is controlled by negative feedback from testosterone and from inhibin, a hormone produced by the [Sertoli cells](#) of the testes. **Review Figures 42.10, 42.11**

Leydig cells The cells between the seminiferous tubules of the testes that secrete testosterone.

Sertoli cells Cells in the seminiferous tubules of the testes that nurture the developing sperm.

► 42.4 Female Sex Organs Produce Eggs and Nurture Embryos

- Primary oocytes in the ovary are surrounded by granulosa and thecal cells that make up a follicle. Each month a small number of follicles respond to pituitary FSH by growing, producing estrogen, and promoting development of the oocyte.
- Usually in each cycle only one follicle fully matures and releases its oocyte, which is picked up by the opening of the oviducts. Sperm deposited in the [vagina](#) during copulation move up through the [cervix](#) and [uterus](#) into the oviducts. Fertilization occurs in the upper regions of the oviducts. **Review Figure 42.12, Activity 42.3**

vagina (vuh jine' uh) [L. sheath] In female animals, the entry to the reproductive tract.

cervix (sir' vix) [L. neck] The opening of the uterus into the vagina.

uterus (yoo' ter us) [L. *utero*: womb] A specialized portion of the female reproductive tract in mammals that receives the fertilized egg and nurtures the embryo in its early development. Also called the womb.

- The maturation and release of eggs constitute an ovarian cycle. The **uterine**, or **menstrual, cycle** prepares the uterus for receipt of a blastocyst. If no blastocyst is implanted, the lining of the uterus sloughs off in the process of [menstruation](#). **Review Focus: Key Figure 42.13, Animation 42.2**

menstruation The process by which the endometrium breaks down, and the sloughed-off tissue, including blood, flows from the body.

- Both the ovarian and the uterine cycles are under the control of hypothalamic and pituitary hormones, which in turn are under the feedback control of estrogen and progesterone. **Review Figure 42.14**
- Childbirth is initiated by hormonal and mechanical stimuli that increase the contractility of uterine muscle. **Review Figures 42.14, 42.15A**

▶ 42.5 Fertility Can Be Controlled

- Methods of [contraception](#) include abstention from copulation and the use of technologies that decrease the probability of fertilization. **Review Table 42.1**

contraception Birth control methods that prevent fertilization or implantation (conception).

- [Assisted reproductive technologies \(ARTs\)](#) have been developed to increase fertility.

assisted reproductive technologies (ARTs) Any of several procedures that remove unfertilized eggs from the ovary, combine them with sperm outside the body, and then place fertilized eggs or egg–sperm mixtures in the appropriate location in a female's reproductive tract for development.

Go to **LearningCurve** (in **LaunchPad**) for dynamic quizzing that helps you solidify your understanding of this chapter. **LearningCurve** adapts to your responses, giving you the practice you need to master each key concept.

Review

2.4 The ovarian and uterine cycles are coordinated and timed by the same hormones that initiate sexual maturation.

Original Paper: Johnston, S. D., P. O'Callaghan, K. Nilsson, G. Tzipori and J. D. Curlewis. 2004. Semen-induced luteal phase and identification of a LH surge in the koala (*Phascolarctos cinereus*). *Reproduction* 128: 629-634.

Many female mammals, including humans, are spontaneous ovulators, meaning they ovulate in a cyclical pattern; the release of eggs requires no external stimulus. Other female mammals, including camels, rabbits, and koalas, are reflex ovulators; in these females, sexual activity induces ovulation. The females come into estrus but do not ovulate and progress to the luteal phase unless copulation occurs. What is the ovulation “trigger” in these mammals? Is it a pheromone, the physical stimulus of coitus, or a chemical signal in the seminal fluid? Researchers studied female koalas to find the answer.

The goal of Experiment 1 was to determine whether the presence of a male or the physical act of mating stimulates ovulation. Female koalas were separated into two groups of four. On day 2 of estrus, Group A females were paired with males, and mating occurred. Group B females were housed next to males but without physical contact. At intervals following initiation of exposure to males, the researchers took blood samples from the females and measured luteinizing hormone (LH) as the indicator of ovulation. The results of the blood samples indicated that all four females in Group A showed 25 nanogram per milliliter (ng/mL) peaks of LH between 24 and 32 hours postcoitus, and all gave birth 35 days postcoitus. During the same time interval, no females in Group B showed any change in LH hormone levels, and none gave birth.

In Experiment 2, female koalas were separated into four groups of nine. On day 2 of estrus, Group A females underwent an artificial insemination procedure but received 1 mL of 0.9% sterile saline. Group B females were artificially inseminated with 1 mL of koala semen. Group C females had their urogenital sinus artificially stimulated with a glass rod designed to mimic the action of a male koala's penis during mating. Group D females had the same treatment as females in Group C, followed by artificial insemination with 1 mL of koala semen. At 14 and 28 days after the treatments, the researchers took blood samples from the females and measured levels of progesterone as an indicator of the postovulatory luteal phase. The mean values of blood progesterone levels were calculated for each group and are shown in the figure below.

Questions

1. Describe the series of events in a female koala's body that would produce the results in Experiment 1. What potential triggers of ovulation could be eliminated through this experiment?
2. Based on the results of Experiment 2, what appears to be the necessary and sufficient stimulus for reflex ovulation in the koala? What potential triggers of ovulation could be eliminated through this experiment?
3. Propose a possible evolutionary advantage of reflex versus spontaneous ovulation.

Go With the Flow

Place your hand over your heart. Point to your appendix, then your pancreas. Surely your hand went to the left side of your chest, then to the right side of your lower abdomen, and lastly to the left side of your upper abdomen. Vertebrates are bilaterally symmetrical, but our symmetry is not absolute. Some internal organs are oriented to the left and some to the right. In about 1 out of every 7,000 people, these orientations are reversed, a condition known as situs inversus (“location inverted”). The difference arises from events very early in the development of the embryo. Most people with situs inversus lead normal lives and are unaware of their condition until they have diagnostic imaging or surgery.

You will learn in this chapter that a mammalian embryo goes from a single layer of cells to the next stage, with two layers of cells, by forming a midline slit, and that cells migrate through that slit to form a second cell layer. Below where the inward movement of cells starts is an area called the node. Each cell at the node has a primary cilium. The primary cilia of some of these cells are nonmotile and probably serve sensory functions. The primary cilia of other nodal cells are motile, and they beat in a clockwise motion that moves extracellular fluid across the surface of the node. That fluid movement is from right to left. Why?

Imagine that the movement of a cilium describes a clock face oriented so that 12 o’clock is closest to the embryo’s future head. The cilia protrude from the cell surfaces at an angle pointing posteriorly. Thus when the cilia rotate through the 6 o’clock position, they are closer to the cell surface and experience greater resistance than at the 12 o’clock position. As a result, the circular beating of cilia at this critical spot—the node—creates left–right flow and therefore left–right positional information.

Why do we hypothesize that the information generated by beating nodal cilia is responsible for left–right asymmetrical patterns? In mutant strains of mice that have no cilia or only nonmotile cilia in the node, about half of the mice have reversed organ symmetry. Similarly, about half of the people with Kartagener’s syndrome, a spectrum of rare genetic disorders in humans characterized by nonmotile cilia, have situs inversus.

QA How does the embryo know left from right?

43.1 Fertilization Activates Development

Fertilization is the joining of sperm and egg to produce a diploid zygote. You might think of fertilization as the event that begins development. But keep two things in mind: (1) in asexually reproducing animals, development proceeds without fertilization, and (2) in animals where fertilization does occur, it is preceded by critical events in the maturing egg that influence subsequent development. Thus in studying fertilization we are asking how it activates multicellular development in sexually reproducing animals.

focus your learning

The egg and sperm contribute different materials to the zygote.

Sperm entry converts the symmetry of the frog egg from radial to bilateral.

The movement of cytoplasm, proteins, and organelles following fertilization changes the distribution of critical signaling factors.

Fertilization does more than restore a full diploid complement of maternal and paternal genes. The fusion of sperm and egg cell membranes:

- triggers ion fluxes across the egg membrane.

- creates blocks to the entry of additional sperm into the egg.

- changes the pH of the egg cytoplasm.

- increases egg metabolism and stimulates protein synthesis.

- initiates the rapid series of cell divisions that produce a multicellular embryo.

We described the mechanisms of fertilization in [Key Concept 42.2](#). Here we will take a closer look at the cellular and molecular interactions of sperm and egg that initiate the first steps of development.

The sperm and the egg make different contributions to the zygote

In most species, eggs are much larger than sperm. Egg cytoplasm is well stocked with organelles, nutrients, and a variety of molecules, including cytoplasmic determinants such as transcription factors and mRNAs (see [Key Concept 19.2](#)). Cytoplasmic determinants in the egg play important roles in setting up the signaling cascades that orchestrate the major events of development: determination, differentiation, morphogenesis, and growth. Nearly everything the embryo needs during its early stages of development comes from the mother, including its mitochondria (and therefore all of its mitochondrial DNA).

In addition to its haploid nucleus, the sperm makes one other crucial contribution to the zygote in most species—the centriole. The centriole contributes to the zygote's centrosome, which organizes the mitotic spindles for subsequent cell divisions (see [Figure 11.9](#)). Centrioles are also the origin of the microtubules of the primary cilia, which are important in cell signaling, as you will see when we return to the opening question about how embryos know left from right.

Fertilization sets the stage for determination

Unique attributes of amphibian eggs make them ideal models for illustrating how

rearrangements of egg cytoplasm set the stage for determination. Remember from [Key Concept 19.1](#) that determination sets the developmental fates of cells, and it precedes differentiation — the expression of different cell properties. The molecules in the cytoplasm of the amphibian egg are not homogeneously distributed. The entry of the sperm into the egg stimulates rearrangements of the egg cytoplasm that introduce additional organization to the egg. Sperm entry establishes the polarity of the zygote, and informational molecules in the egg cytoplasm are organized with respect to that polarity. Therefore, when cell divisions begin, these informational molecules—which guide subsequent development—are not divided equally among daughter cells.

Rearrangement of egg cytoplasm following fertilization is easily observed in some frog species because of pigments in the cytoplasm. The nutrients in an unfertilized frog egg are dense yolk granules that are concentrated by gravity in the lower half of the egg, called **the vegetal hemisphere**. The haploid nucleus of the egg is located at the opposite end, in the [animal hemisphere](#). The outermost (cortical) cytoplasm of the animal hemisphere is more pigmented than the underlying cytoplasm. The vegetal hemisphere is not pigmented. Because of these differences, it is easy to observe how the cytoplasm rearranges when the egg is fertilized.

animal hemisphere The metabolically active upper portion of some animal eggs, zygotes, and embryos; does not contain the dense nutrient yolk. (Contrast with vegetal hemisphere.)

The unfertilized frog egg is radially symmetrical. You can turn it on its vegetal-animal pole axis, and all sides are the same. Sperm-binding sites are localized on the surface of the animal hemisphere. When a sperm binds to and enters the egg, the egg's radial symmetry is converted to bilateral symmetry and a dorsal-ventral axis is created. Cortical cytoplasm rotates toward the site of sperm entry ([Figure 43.1](#)). This rotation brings the animal and vegetal regions of cytoplasm into contact with each other, producing a band of lightly pigmented cytoplasm on the side opposite the site of sperm entry. This band, called the [gray crescent](#), marks the location of important developmental events in some species of amphibians.

Figure 43.1 The Gray Crescent In amphibian eggs, cortical rotation and

rearrangement of the cytoplasm after fertilization create the gray crescent opposite the point of sperm entry. These events are important for specifying the body axes and other important events in later development.

gray crescent In frog development, a band of diffusely pigmented cytoplasm on the side of the egg opposite the site of sperm entry. Arises as a result of cytoplasmic rearrangements that establish the anterior–posterior axis of the zygote.

The centriole that was the sperm's contribution to the egg initiates the cytoplasmic reorganization that coincides with the appearance of the gray crescent. The centriole organizes the microtubules in the vegetal hemisphere cytoplasm into a parallel array that guides the movement of the cortical cytoplasm as well as proteins and organelles.

The movement of cytoplasm, proteins, and organelles changes the distribution of critical signals. A key transcription factor in early development is β -catenin produced from maternal mRNA (mRNA produced and stored in the egg while it was maturing in the ovary). β -catenin is found throughout the egg cytoplasm ([Figure 43.2](#)). Also present throughout the egg cytoplasm is a protein kinase, glycogen synthase kinase-3 (GSK-3), that phosphorylates β -catenin and thereby targets it for degradation. An inhibitor of GSK-3 is localized in the vegetal cortex of the egg. After sperm entry, this inhibitor moves along microtubules to the gray crescent, where it prevents the degradation of β -catenin. As a result, the concentration of β -catenin is higher on the dorsal than on the ventral side of the developing embryo, setting up regional differences within the egg cytoplasm that have developmental consequences.

Figure 43.2 Cytoplasmic Factors Set Up Signaling Cascades Cytoplasmic movement changes the distributions of critical developmental signals. In the frog fertilized egg, the interaction of the protein kinase, the GSK-3 inhibitor, and the protein β -catenin results in differential concentrations of β -catenin in blastomeres following cleavage thereby specifying the dorsal-ventral axis of the embryo.

43.1 recap

The egg is stocked with nutrients and informational molecules that power and direct the early stages of development. Fertilization activates the egg and stimulates rearrangement of the cytoplasm, setting up the body axes and organizing positional information that will control determination and differentiation.

learning outcomes

You should be able to:

- Compare the contributions of the sperm and the egg to the zygote.
- Explain how sperm entry converts frog egg symmetry from radial to bilateral.
- Explain how the distribution of β -catenin in the egg cytoplasm is altered following fertilization and why this alteration is important.

1. Apart from its nucleus, what is the major contribution of the sperm to subsequent cell signaling in the embryo?
2. How is the gray crescent generated in the fertilized frog egg?
3. How does β -catenin become more concentrated on the dorsal side of the amphibian embryo?

The uneven distribution of informational molecules in the cytoplasm of the fertilized egg is essential to later events in development. In the next section you will see how these informational molecules end up in different cells of the developing embryo.

43.2 Mitosis Divides Up the Early Embryo

β -Catenin plays a major role in the cell-cell signaling cascade that begins the process of cell determination and the formation of the embryo. But cell-cell signaling requires more than one cell. The single-celled zygote must become a multicellular embryo.

focus your learning

The three main types of cleavage are complete, incomplete, and superficial.

Mammalian cleavage is unusual because of the requirements associated with the connection between the embryonic and maternal circulatory systems.

Determination can arise from informational molecules present in the egg or by information received by their environment and neighboring cells.

Twins can form in several ways.

Reproductive germ cells are determined very early in cleavage.

Cleavage produces a multicellular embryo

Cleavage is the cell divisions that transform the diploid zygote into a mass of undifferentiated cells that develop as the embryo. Zygote cytoplasm is not homogeneous, and these first cell divisions result in the differential distribution of nutrients and cytoplasmic determinants in the early embryo.

cleavage The first few cell divisions of an animal zygote. (See *also* complete cleavage, incomplete cleavage.)

In most animals, cleavage proceeds with rapid DNA replication and mitosis but with no cell growth and little gene expression. The embryo becomes a solid ball of smaller and smaller cells. Eventually this ball forms a central fluid-filled cavity called a **blastocoel**, and the embryo is called a **blastula**. Its individual cells are called **blastomeres**. The pattern of cleavage in different species influences the form of their blastulas.

blastocoel (blass' toe seal) [Gk. *blastos*: sprout + *koiolos*: hollow] The central, hollow cavity of a blastula.

blastula (blass' chu luh) An early stage of the animal embryo; in many species, a hollow sphere of cells surrounding a central cavity, the blastocoel. (Contrast with blastodisc.)

blastomere Any of the cells produced by the early divisions of a fertilized animal egg.

Complete cleavage occurs in eggs that have little yolk such as the eggs of mammals. Early cleavage furrows divide the egg completely. The amphibian egg undergoes complete cleavage, but vegetal pole yolk causes unequal cytoplasm division and animal hemisphere blastomeres are smaller than those in the vegetal hemisphere (**Figure 43.3A**).

complete cleavage Pattern of cleavage that occurs in eggs that have little yolk. Early cleavage furrows divide the egg completely, and the blastomeres are of similar size. (Contrast with incomplete cleavage.)

(A) Complete cleavage (frog)

The first **cleavage** passes through the poles and site of sperm entry and bisects the gray crescent.

The second cleavage is at right angles to the first.

The third cleavage is at right angles (horizontal) to the first two and separating the animal and vegetal hemispheres. Vegetal hemisphere cells are larger.

The embryo forms as a **blastodisc** that sits on top of the yolk mass.

(B) Incomplete cleavage (zebrafish)

In birds and fishes, cleavage furrows do not penetrate the large yolk mass.

(C) Superficial cleavage (fruit fly)

1 Mitosis (nuclear division) occurs without cell division.

3 The nuclei migrate to the edge of the cell membrane.

2 A **syncytium**—a single cell with many nuclei—is produced.

4 Cellularization occurs, creating a **blastoderm**.

Figure 43.3 Some Patterns of Cleavage Differences in patterns of early embryonic development reflect differences in the way the egg cytoplasm is organized. **(A)** The frog is a model organism representing complete cleavage in these scanning electron micrographs (SEMs). **(B)** SEMs of zebrafish embryos illustrate incomplete cleavage, in which the large yolk mass limits the planes of cleavage. **(C)** Nuclear staining reveals the syncytial nuclei characteristic of the early embryo of a fruit fly. These nuclei migrate to the periphery. Cleavage furrows then move inward to separate the nuclei into individual cells, forming the blastoderm.

Incomplete cleavage occurs in eggs with a lot of yolk and the cleavage furrows do not penetrate it completely. **Discoidal cleavage** is a type of incomplete cleavage common in fishes as well as in birds and other reptiles, in which the embryo forms as a disc of cells, or blastodisc, that sits on top of the dense yolk mass (**Figure 43.3B**).

incomplete cleavage A pattern of cleavage that occurs in many eggs that have a lot of yolk, in which the cleavage furrows do not penetrate all of it. (See *also* discoidal cleavage, superficial cleavage. Contrast with complete cleavage.)

discoidal cleavage In animal development, a type of incomplete cleavage that is common in fishes, reptiles, and birds, the eggs of which contain a dense yolk mass.

Superficial cleavage is a variation of incomplete cleavage that occurs in insects such as the

fruit fly (*Drosophila*). Early in development, cycles of mitosis occur without cell division, producing a **syncytium**—a single cell with many nuclei (**Figure 43.3C**). The nuclei eventually migrate to the periphery of the egg, after which the cell membrane of the egg grows inward, creating a **blastoderm** by partitioning the nuclei into individual cells surrounding a core of yolk.

superficial cleavage A variation of incomplete cleavage in which cycles of mitosis occur without cell division, producing a syncytium (a single cell with many nuclei).

syncytium A single cell with many nuclei produced as a result of superficial cleavage.

blastoderm A layer of undifferentiated cells that are a very early stage of development prior to the specification of the embryonic axis.

The positions of the mitotic spindles during cleavage are not random but are defined by ***cytoplasmic determinants** produced from the maternal genome and stored in the egg. The orientation of the mitotic spindles can determine the planes of cleavage and the arrangement of the blastomeres.

In complete cleavage, if the mitotic spindles of successive cell divisions form parallel or perpendicular to the animal-vegetal axis of the zygote, a pattern of **radial cleavage** occurs. The first two cell divisions are parallel to the animal-vegetal axis, and the third is perpendicular to it (see **Figure 43.3A**). **Spiral cleavage** results when the mitotic spindles are at oblique angles to the animal-vegetal axis. In spiral cleavage, each new cell layer is shifted to the left or right, depending on the orientation of the mitotic spindles. Most mollusks have spiral cleavage, reflected in some species by a coiling shell pattern (as seen in snails).

radial cleavage Embryonic development in which the planes of cell division are parallel and perpendicular to the animal-vegetal axis of the embryo. (Compare to spiral cleavage.)

spiral cleavage A form of complete cleavage in which the cleavage planes are at oblique angles to the animal-vegetal axis.

Cleavage in mammals is unique

Several features of early cell divisions in placental mammals (eutherians) are very different from those seen in other animal groups. First, this process in mammals is very slow. Cell divisions are 12 to 24 hours apart, compared with tens of minutes to a few hours in non-mammalian species. Also, the cell divisions of mammalian blastomeres are not in synchrony with each other. Because the blastomeres do not undergo mitosis at the same time, the number of cells in the embryo does not increase in the regular progression (2, 4, 8, 16, 32, etc.) typical of other species. The slowness of mammalian cleavage means that genes expressed during cleavage can play roles in cleavage. In animals such as sea urchins and frogs where cleavage progresses rapidly, very little if any gene transcription occurs in the blastomeres. Instead, cleavage is directed by molecules that were present in the egg before fertilization.

The pattern of mammalian cleavage is unique and is called **rotational cleavage**. The first cell division is parallel to the animal-vegetal axis as in radial cleavage, but in the second cell division, the two blastomeres divide at right angles to one other. One blastomere divides parallel to the animal-vegetal axis, while the other divides perpendicular to this axis (**Figure 43.4A**). As in other animals that have complete cleavage, the early cell divisions in a mammalian zygote produce a loosely associated ball of cells. After the 8-cell stage, however, the behavior of the mammalian blastomeres changes. They change shape to maximize their surface contact with one another, form tight junctions (see **Figure 6.7**), and become a compact mass of cells (**Figure 43.4B**).

rotational cleavage The form of complete cleavage that occurs in mammals. The first cleavage plane is parallel to the animal–vegetal axis and the two second cleavage planes are at right angles to each other.

(A) Mammalian rotational cleavage

Bleb

16-Cell stage

Compacted cells

(C) Cross section of a mammalian blastocyst

Figure 43.4 Becoming a Blastocyst (A) Mammals have rotational, complete cleavage, in which the plane of the first cleavage is parallel to the animal-vegetal (A-V) axis, but the second cell division involves two planes (beige) at right angles to each other. (B) Scanning electron micrographs (color added) of early cleavage (leading to the formation of the blastocyst) in a human embryo. The cells' outer surfaces are covered with cilia (bright yellow). The small spheres, or "blebs," of cytoplasmic material, prominent at the 8-cell stage, disintegrate as cleavage progresses. (C) Seen in cross section under a light microscope, a mammalian blastocyst consists of an inner cell mass adjacent to a fluid-filled blastocoel and surrounded by trophoblast cells.

Soon after the transition to the 32-cell stage, the cells of the mammalian embryo separate into two groups. The **inner cell mass** will develop as the embryo, while the surrounding outer cells become an encompassing sac called the **trophoblast**. Trophoblast cells secrete fluid, creating a cavity—the blastocoel—with the inner cell mass at one end. At this stage the mammalian embryo is called a **blastocyst**, distinguishing it from the blastulas of other animal groups (**Figure 43.4C**). The pluripotent cells of the inner cell mass are known as **embryonic stem cells** and are the subject of much research because of their therapeutic potential (see **Key Concept 19.1**).

inner cell mass Derived from the mammalian blastula (blastocyst), the inner cell mass that will give rise to the yolk sac (via hypoblast) and embryo (via epiblast).

trophoblast [Gk *trophes*: nourishment + *blastos*: sprout] At the 32-cell stage of mammalian development, the outer group of cells that will become part of the placenta and thus nourish the growing embryo. (Contrast with inner cell mass.)

blastocyst (blass' toe cist) An early embryo formed by the first divisions of the fertilized egg (zygote). In mammals, a hollow ball of cells.

embryonic stem cell (ESC) A pluripotent cell in the blastocyst.

Why is mammalian cleavage so different? A key factor is that mammalian eggs contain little or no yolk and must derive all nutrients from the mother. To support the developing embryo, a connection develops between the circulatory systems of the embryo and the mother. As you will see later in this chapter, the structures that provide this connection are the placenta and the umbilical cord. Thus the blastocyst of placental mammals must produce both the embryo (from the inner cell mass) and its support structures (from the trophoblast).

Fertilization in mammals occurs in the upper reaches of the oviduct, and cleavage occurs as the zygote travels down the oviduct to the uterus (**Figure 43.5**). When the blastocyst arrives in the uterus, the trophoblast adheres to the lining of the uterus (the **endometrium**), beginning the process of **implantation**. In humans, implantation begins about 6 days after fertilization and is aided by adhesion molecules and enzymes secreted by the trophoblast.

Figure 43.5 A Human Blastocyst at Implantation Adhesion molecules and proteolytic enzymes secreted by trophoblast cells allow the blastocyst to burrow into the endometrium. Once the blastocyst is implanted in the wall of the uterus, the trophoblast cells send out numerous projections—the chorionic villi—which increase the embryo’s area of contact with the mother’s bloodstream. The inner cell mass

divides into two embryonic tissues, the hypoblast and the epiblast. The epiblast splits to form the amniotic cavity.

endometrium The epithelial lining of the uterus.

implantation The process by which the early mammalian embryo becomes attached to and embedded in the lining of the uterus.

As the blastocyst moves down the oviduct to the uterus, it must not embed itself in the oviduct (Fallopian tube) wall, or the result will be an ectopic, or tubal, pregnancy—a very dangerous condition. Early implantation is prevented by the zona pellucida that surrounded the egg (see [Figure 42.6](#)) and remains around the cleaving ball of cells. At about the time the blastocyst reaches the uterus, it hatches from the zona pellucida so implantation can occur.

The fates of blastomeres depend on the cytoplasm they receive during cleavage

Cleavage results in a repackaging of the egg cytoplasm into a large number of small cells surrounding the fluid-filled blastocoel. Except in mammals, there is little gene expression during early cleavage divisions. Cells in different regions of the blastula do, however, possess different complements of the nutrients and cytoplasmic determinants that were present in the egg. For example, [Figure 43.2](#) illustrated the processes by which β -catenin becomes localized in the region of the amphibian zygote that will become the dorsal side of the embryo.

The blastocoel prevents cells from different regions of the blastula from coming into contact and interacting, but that will soon change. During the next stage of development, the cells of the blastula move around and come into new associations with one another, communicate instructions to one another, and begin to differentiate. In many animals, these movements of the blastomeres are so regular and well orchestrated that it is possible to label specific blastomeres with a dye, thus producing [fate maps](#) that identify the tissues and organs formed from each blastomere's progeny ([Figure 43.6](#)).

fate map A diagram of the blastula showing which cells (blastomeres) are “fated” to contribute to specific tissues and organs in the mature body.

Figure 43.6 Fate Map of a Typical Amphibian Blastula

Blastomeres become **determined**—committed to specific fates—at different times in different species. In some species, such as roundworms, the fates of blastomeres are restricted as early

as the two-cell stage. This early determination depends on informational molecules that were originally present in the egg cytoplasm and is called **autonomous specification**. If one of these blastomeres is experimentally removed, a particular portion of the embryo will not form. The resulting developmental pattern has been called **mosaic development** because each blastomere seems to contribute a specific set of “tiles” to the final “mosaic” that is the adult animal. Mosaic development is the common form of development in invertebrates.

autonomous specification Determination of cell fates due to informational molecules originally present in the egg.

mosaic development Pattern of animal embryonic development in which each blastomere contributes a specific part of the adult body. (Contrast with regulative development.)

The fates of blastomeres in most vertebrate embryos are determined by information they receive from their environment and their neighboring cells. This mechanism of determination is called **regulated specification**, and it gives rise to **regulative development**. Unlike in mosaic development, the loss of some cells during cleavage in regulative development does not affect the developing embryo, because the remaining cells compensate for the loss. A subset of the remaining cells may add a cell division, or they may even change their fate to compensate for the cells lost. Because development is regulative in humans, a single blastomere can be removed from early embryos without harming the remaining blastomeres or disrupting normal development. Cells removed from embryos produced by in vitro fertilization can be used for preimplantation genetic diagnosis to ensure that healthy embryos are selected for implantation in the mother.

regulated specification Determination of cell fates due to signals mostly received from neighboring cells.

regulative development A pattern of animal embryonic development in which the fates of the first blastomeres are not absolutely fixed. (Contrast with mosaic development.)

If some blastomeres can change their fate to compensate for the loss of other cells during cleavage and blastula formation, can those cells form an entire embryo? Yes, in species with regulative development, they can. If during cleavage or early blastula formation, the blastomeres are physically separated into two groups, both groups can produce complete embryos. Since the two embryos come from the same zygote, they will be monozygotic twins—genetically identical.

Non-identical twins occur when two separate eggs are fertilized by two separate sperm. Thus, although identical twins are always the same sex, non-identical twins have a 50 percent chance of being the same sex (that is, the same as two non-twin siblings). If genetic or environmental factors cause the blastula or blastocyst to split partially, the result is twins who are conjoined at some point on their bodies and usually share some of their organs and limbs. Conjoined twins occur in about 1 out of 50,000 human pregnancies.

Reproductive germ cells are determined early in cleavage

Molecules present in the egg cytoplasm determine which lineage of cells will eventually populate the gonads and become the reproductive stem cells—oogonia and spermatogonia. In fruit flies, at the ninth nuclear division (recall that the egg is a multinucleate syncytium at this stage; see [Figure 43.3C](#)), a group of nuclei migrate to the posterior pole of the egg where they become surrounded by **pole plasm**—cytoplasm containing a complex mixture of fibrils, mitochondria, and specific proteins and mRNAs. As the cellularization of the blastoderm proceeds, the nuclei

within the pole plasm give rise to the lineage of cells that will eventually migrate to the gonads (when they form) and produce germ cells (eggs and sperm).

pole plasm Cytoplasm at one end of an insect egg that determines that the cells that form at that location will become germ cells.

As in fruit flies, the germ cell lineage in frogs starts with a special type of cytoplasm—the germ cell plasm—localized to one part of the egg. As a result of cleavage, the germ cell plasm becomes enclosed within some of the cells in the vegetal hemisphere; descendants of these cells will eventually migrate to the gonads once those structures form. The components of germ cell plasm have not been fully characterized, but one hypothesis is that they include inhibitors of transcription and translation that prevent these cells from differentiating into anything other than germ cells.

43.2 recap

Cleavage divides up the cytoplasm of the zygote such that different blastomeres contain different combinations of informational molecules. The amount of nutrients stored in the egg influences the pattern of cell cleavage that produces the blastula. Blastulation in mammals is different compared to other vertebrates. The cells that will give rise to germ cell lineages are set aside very early in development.

learning outcomes

You should be able to:

- Compare the three main types of cleavage.
- Explain why cleavage in mammals is different from other vertebrates.
- Compare and contrast regulated and autonomous specification.
- Compare and contrast identical and non-identical twins.
- Compare the timing of determination in reproductive germ cells with that in other types of cells in the embryo.

1. What characteristic of the eggs of different species relates to whether cleavage is complete or incomplete?
2. Why can genes expressed during cleavage play roles in development in mammals but not in sea urchins and frogs?
3. Why can identical twins arise from a single egg in mammals but not in most invertebrates?
4. Why is there a longer time between determination and differentiation in germ cells versus skin cells?

Of the next stage of development—gastrulation—the developmental biologist Lewis Wolpert once said, “It is not birth, marriage, or death, but gastrulation which is the most important time in your life.” During gastrulation, cell movements create new cell-to-cell contacts, which in turn set up signaling cascades that initiate the differentiation of cells and tissues and set the stage for the emergence of the body plan.

43.3 Gastrulation Generates Multiple Tissue Layers

The blastula is typically a fluid-filled ball of cells. How does this simple ball of cells become an embryo made up of multiple tissue layers with head and tail ends and dorsal and ventral sides? **Gastrulation** is the process whereby the blastula is transformed by massive movements of cells into an embryo with multiple tissue layers and distinct body axes. The resulting spatial relationships between tissues make possible the inductive interactions between cells that trigger differentiation and organ formation.

gastrulation Development of a blastula into a gastrula. In embryonic development, the process by which a blastula is transformed by massive movements of cells into a gastrula, an embryo with three germ layers and distinct body axes.

focus your learning

Cell movements during gastrulation result in three germ layers and new tissue interactions.

Gastrulation in frogs is more complex than in sea urchins, owing to frog blastulas having more yolk and more cell layers.

The dorsal lip of the blastopore is the primary organizer in the amphibian embryo.

Showing that a protein is an inductive signal requires that it be both necessary and sufficient for the proposed effect.

In amphibians, organizer cells moving anteriorly from the dorsal lip of the blastopore initiate the formation of different organs along the anterior-posterior axis.

Inductive tissue interactions can suppress as well as activate.

Because bird and reptile eggs have a large yolk mass, the embryos have a flattened blastodisc, and display a pattern of gastrulation very different from that of amphibians.

In the triploblastic animals (see [Key Concept 30.1](#)), three **germ layers** (also called cell layers or tissue layers, and not to be confused with germ cells) form during gastrulation:

germ layers The three embryonic layers formed during gastrulation (ectoderm, mesoderm, and endoderm). Also called cell layers or tissue layers.

- The **endoderm** is the innermost germ layer, created as some blastomeres move to the inside of the embryo. The endoderm gives rise to the epithelial lining of the digestive tract, respiratory tract, pancreas, thyroid, and liver.

endoderm [Gk. *endo*: within + *derma*: skin] The innermost of the three embryonic germ layers delineated during gastrulation. Gives rise to the digestive and respiratory tracts and structures associated with them.

- The **ectoderm** is the outer germ layer, formed from those cells remaining on the outside of the embryo. The ectoderm contributes to the nervous system, including the eyes and ears; and to the epidermal layer of the skin and structures derived from skin, such as hair, feathers, nails or claws, sweat glands, oil glands, and even teeth and other tissues of the mouth.

ectoderm [Gk. *ektos*: outside + *derma*: skin] The outermost of the three embryonic germ layers first delineated during gastrulation. Gives rise to the skin, sense organs, and nervous system.

- The **mesoderm** is the middle layer and is made up of cells that migrate between the endoderm and the ectoderm. The mesoderm contributes tissues to many organs, including the heart, blood vessels, muscles, and bones.

mesoderm [Gk. *mesos*: middle + *derma*: skin] The middle of the three embryonic germ layers first delineated during gastrulation. Gives rise to the skeleton, circulatory system, muscles, excretory system, and most of the reproductive system.

The three germ layers are illustrated for a very early embryo in the fate map shown in [Figure 43.6](#).

Some of the most interesting and important challenges in animal development have dealt with two related questions: what directs the cell movements of gastrulation, and what is responsible for the resulting patterns of cell differentiation and organ formation? Scientists have made significant progress in answering both these questions at the molecular level. In the following discussion we will begin with sea urchin gastrulation because it is the simplest to conceptualize in spatial terms. We will then describe the more complex pattern of gastrulation in frogs, and then the still more complex patterns in reptiles (including birds), and mammals.

 Animation 43.1 **Gastrulation** www.Life11e.com/a43.1

Invagination at the vegetal pole initiates gastrulation in the sea urchin

The sea urchin blastula is a hollow ball of cells only one cell layer thick. At the end of blastulation the rate of mitosis slows, and the beginning of gastrulation is marked by a flattening of the vegetal hemisphere (**Figure 43.7**). Some cells at the vegetal pole break away from neighboring cells and migrate into the cavity to become **mesenchyme**—cells of the middle germ layer, the mesoderm. Mesenchymal cells are not organized in tightly packed sheets or tubes like epithelial cells are; they act as independent units, migrating into and among the other tissue layers. These early mesenchymal cells will contribute to the skeletal structures of the sea urchin.

Figure 43.7 Gastrulation in Sea Urchins During gastrulation, cells move to new positions and form the three germ layers from which differentiated tissues develop.

Q: How do cells on the surface of the vegetal pole become the cells lining the gut?

mesenchyme (mez' en kyme) [Gk. *mesos*: middle + *enchyma*: infusion] Embryonic or unspecialized cells derived from the mesoderm.

The flattening at the vegetal pole results from changes in the shape of individual blastomeres. These cells, which are originally rather cuboidal, become wedge-shaped, with smaller outer edges and larger inner edges. As a result, the vegetal pole bulges inward, or invaginates, as if someone were poking a finger into a hollow ball (see [Figure 43.7](#)). The invaginating cells become endoderm and form the primitive gut, called the [archenteron](#). The archenteron begins as a short stubby invagination, but its cells extend, flatten, interdigitate, and migrate over one another to form a long thin tube. This process is called [convergent extension](#). As the archenteron gets closer to the opposite side of the blastocoel, more mesenchymal cells migrate out of it into the blastocoel. These cells remain attached to the tip of the archenteron and send out extensions called filopodia that adhere to the overlying ectoderm. The filopodia contract and pull the archenteron toward the overlying ectoderm. The mouth of the animal will form where the archenteron makes contact with this overlying ectoderm. The opening created by the invagination of the vegetal pole is called the [blastopore](#), and it will become the anus of the animal.

archenteron (ark en' ter on) [Gk. *archos*: first + *enteron*: bowel] The earliest primordial animal digestive tract.

convergent extension Movements of cells in the sea urchin blastula that form the archenteron. These cells elongate, flatten, and interdigitate to form a tubular structure.

blastopore The opening created by the invagination of the vegetal pole during gastrulation of animal embryos.

We should recall at this point that where the mouth and anus form during gastrulation distinguishes the two major groups of animals that have bilateral symmetry, the protostomes and the deuterostomes (see [Key Concept 30.1](#)). If the blastopore becomes the mouth, the animals are classified as protostomes ("mouth first"), and if the blastopore becomes the anus, the animals are classified as deuterostomes ("mouth second").

What mechanisms control the various cell movements of sea urchin gastrulation? The immediate answer is that specific properties of particular blastomeres change. For example, some vegetal cells change shape and bulge into the blastocoel, and these cells become mesenchyme. Once they lose contact with their neighboring cells on the surface of the blastula, they send out filopodia that then move along an extracellular matrix of proteins laid down by the cells lining the blastocoel.

A deeper understanding of gastrulation requires that we discover the molecular mechanisms whereby different blastomeres develop different properties. Cleavage systematically divides the cytoplasm of the egg. The sea urchin blastula at the 64-cell stage is radially symmetrical, but it has polarity, as described in [Key Concept 19.2](#). It consists of tiers of cells. As in the frog blastula, the top is the animal pole and the bottom the vegetal pole.

If different tiers of blastula cells are separated experimentally, they show different developmental potentials; only cells from the vegetal pole are capable of initiating the development of a complete larva. It has been proposed that these differences are due to uneven

distribution of various transcriptional regulatory proteins in the egg cytoplasm. As cleavage progresses, these proteins end up in different groups of cells. Therefore specific sets of genes are activated in different cells, determining their different developmental capacities.

Next we will turn to gastrulation in the frog and to the key signaling molecules involved.

Frog gastrulation begins at the gray crescent

Amphibian blastulas have considerable yolk and are more than one cell layer thick; gastrulation is therefore more complex in amphibians than in sea urchins. Variation is considerable across different species of amphibians, so this brief account combines results from studies done on different species to produce a generalized picture of amphibian development.

Amphibian gastrulation begins when certain cells in the gray crescent region (see [Figure 43.1](#)) change their shapes and cell-adhesion properties. These cells bulge inward toward the blastocoel while they remain attached to the outer surface of the blastula by slender necks; because of their shape, they are called bottle cells. Bottle cells mark the spot where the **dorsal lip** of the blastopore will form (**Focus: Key Figure 43.8**).

dorsal lip In amphibian embryos, the dorsal segment of the blastopore. Also called the organizer, this region directs the development of nearby embryonic regions.

focus: key figure

Figure 43.8 Gastrulation in the Frog Embryo Yellow, blue, green, and red in this diagram are matched to those colors in [Figure 43.6](#), the frog fate map.

Q: Epiboly results in the formation of which tissues in the adult frog?

 Media Clip 43.1 **Frog Gastrulation Time-Lapse** www.Life11e.com/mc43.1

As the bottle cells move inward, the dorsal lip is created, and a sheet of cells moves over it into the blastocoel. This process is called **involution**. One group of involuting cells is the prospective endoderm; these cells form the primitive gut, or archenteron. Another group will move between the endoderm and the outermost cells to form mesoderm. As with the extension of the archenteron in the sea urchin, these cell rearrangements involve convergent extension. The cells elongate in the direction of growth, but they also intercalate (move in between each other). As gastrulation proceeds, cells from the animal hemisphere flatten and move toward the site of involution in a process called **epiboly**. The blastopore lip widens and spreads ventrally, and eventually forms a complete circle surrounding a “plug” of yolk-rich cells. As cells continue to move inward through the blastopore, the archenteron grows, gradually displacing the blastocoel.

involution Cell movements that occur during gastrulation of frog embryos, giving rise to the archenteron.

epiboly The movement of cells over the surface of the blastula toward the forming blastopore.

As gastrulation comes to an end, the amphibian embryo consists of three germ layers: ectoderm on the outside, endoderm on the inside, and mesoderm in between. The embryo also has a dorsal-ventral and anterior-posterior organization. Most important, the fates of specific regions of the endoderm, mesoderm, and ectoderm have been determined. The beautiful experiments revealing how determination takes place in the amphibian embryo are an old but exciting story.

The dorsal lip of the blastopore organizes the formation of the amphibian embryo

In the early 1900s the German biologist Hans Spemann was studying the development of salamander eggs. He was interested in finding out whether the nuclei of blastomeres remain capable of directing the development of complete embryos or whether these nuclei lose some developmental potential. With great patience and dexterity, he formed loops from single hairs taken from a baby (in fact, his daughter) and tied them around fertilized eggs along the plane of the first cell division, effectively dividing the eggs in half, with the nucleus restricted to one side. The side containing the nucleus went through cell divisions and developed into a salamander; the other half simply degenerated. Up until the 16-cell stage, if one nucleus escaped to the other side of the constriction, twin salamanders could develop. Thus each of the nuclei of the blastula (at least up to the 16-cell stage) was capable of directing and supporting development of the whole organism (regulative development).

As often happens in science, Spemann's bisection experiments revealed a new phenomenon. Sometimes the half of the blastula receiving an escaped nucleus did not develop. When his loops bisected the gray crescent, both halves of the zygote developed into a complete embryo. When he tied the loops so the gray crescent was on only one side of the constriction, however, only that half of the zygote developed into a complete embryo ([Figure 43.9](#)). When the half lacking gray crescent material received a nucleus, it underwent cell division but formed only a clump of undifferentiated cells that Spemann called a "belly piece." Spemann hypothesized that cytoplasmic factors unequally distributed in the fertilized egg were necessary for gastrulation and the development of a normal salamander.

Figure 43.9 Gastrulation and the Gray Crescent Spemann's research revealed that gastrulation and subsequent normal development in salamanders depend on cytoplasmic determinants localized in the region of the blastula that corresponds to the gray crescent region in the fertilized egg.

To further test the hypothesis that cells receiving different complements of cytoplasmic factors had different developmental fates, Spemann transplanted pieces of early gastrulas to various locations on other gastrulas. Guided by fate maps (see [Figure 43.6](#)), he was able to take a piece of ectoderm he knew would develop into the epidermis of the skin and transplant it to a region that normally becomes part of the nervous system, and vice versa.

When he performed these transplants in early gastrulas—when the blastopore was just beginning to form—the transplanted pieces always developed into tissues that were appropriate for the location where they were placed. Transplanted cells destined to become epidermis in their original location developed into nervous system tissue, and transplanted cells destined to become nervous system tissue in their original location developed into host epidermis. Thus Spemann learned that the fates of the transplanted cells had not been determined before the transplantation.

In late gastrulas, however, the same experiment yielded opposite results. Transplanted cells destined to become epidermis in their original location produced patches of skin cells in the host

nervous system, and the transplanted cells from regions that would develop into nervous system tissue produced nervous tissue in the skin of the recipient. At some point during gastrulation, the fates of the embryonic cells had become determined.

Spemann's next experiment, done with his student Hilde Mangold, produced momentous results: they transplanted the dorsal lip of the blastopore (**Figure 43.10**). When this small piece of tissue was transplanted into the presumptive belly area of another gastrula, it stimulated a second site of gastrulation—and a second complete embryo formed belly-to-belly with the original embryo. Because the dorsal lip of the blastopore was apparently capable of inducing the host tissue to form an entire embryo, Spemann and Mangold called the dorsal lip tissue the **primary embryonic organizer**, or simply the **organizer**. For almost 100 years, what has come to be called the Spemann organizer has been an active area of research.

primary embryonic organizer See organizer.

organizer Region of the early amphibian embryo that directs early embryonic development. Also known as the primary embryonic organizer.

Transcription factors and growth factors underlie the organizer's actions

With the advent of modern molecular methods, the primary embryonic organizer has been studied intensively to discover the molecular mechanisms involved in its action. The distribution of the transcription factor β -catenin in the late blastula corresponds to the location of the

organizer in the early gastrula, so β -catenin is a candidate for the initiator of organizer activity. To prove that a protein is an inductive signal, it has to be shown that it is both **necessary** and **sufficient** for the proposed effect. In other words, the effect should not occur if the candidate protein is not present (necessity), and the candidate protein should be capable of inducing the effect where it would otherwise not occur (sufficiency).

The criteria of necessity and sufficiency have been satisfied for β -catenin. If β -catenin mRNA transcripts are depleted by injections of antisense RNA into the egg (see [Key Concept 18.4](#)), gastrulation does not occur. If β -catenin is experimentally overexpressed in another region of the blastula, it can induce a second axis of embryo formation, as the transplanted dorsal lip did in the Spemann-Mangold experiments. Thus β -catenin appears to be both necessary and sufficient for the formation of the primary embryonic organizer—but it is only one component of a complex signaling process. How the presence of β -catenin creates the organizer, and how the organizer then induces the beginnings of the body plan, involves a complex series of interactions between transcription factors and growth factors that control gene expression.

Properties of organizer cells change as they migrate from the dorsal lip

Organizer cells begin the process of formation of the dorsal lip of the blastopore. Specifically, these cells are at the center of the dorsal lip and involute, moving forward on the midline (i.e., the middle of the anterior-posterior axis). The first organizer cells to enter the embryo migrate anteriorly to become the head endoderm and head mesoderm. Here they induce neighboring cells to participate in making structures of the head. Organizer cells that involute later in gastrulation induce structures of the trunk, and the last of the organizer cells to move inward from the dorsal lip induce structures of the tail. How do the organizer cells change to enable them to induce head, trunk, or tail structures?

Inductive tissue interactions can suppress as well as activate. Goosecoid is a transcription factor expressed by early organizer cells. Goosecoid activates genes encoding certain signaling factors. As the early organizer cells move forward in the blastocoel, they come into contact with new populations of cells that produce several different growth factors. For head structures to form, certain of these growth factors have to be suppressed. The most anterior organizer cells, under the influence of Goosecoid, produce and release antagonists to those growth factors.

The induction of trunk structures requires suppression of a different set of growth factors. In organizer cells that involute later than the head organizers, Goosecoid is no longer the dominant transcription factor, and these cells express different growth factor antagonists. The induction of tail structures requires still different activities of the organizer cells that involute last. Thus the organizer cells express appropriate sets of growth factor antagonists at the right times to achieve different patterns of differentiation on the anterior-posterior axis.

The initiation of nervous system development also involves a suppressive tissue interaction. For a long time it was thought that the involuting organizer cells actively induced the overlying ectoderm to form nervous tissue rather than becoming epidermis. We now know, however, that epidermis is not the default state of the dorsal ectoderm. Rather, the underlying mesoderm secretes factors called BMP proteins that induce the ectoderm to become epidermis. The role of the involuting organizer cells is to block that induction, allowing the overlying ectodermal cells to follow what is really their default pathway—differentiation into nervous tissue.

The amount of yolk influences gastrulation

The eggs of reptiles, including birds, contain a mass of yolk, and the blastulas of these groups develop as a disc of cells on top of the yolk (see [Figure 43.3B](#)). We will use the chicken egg to show how gastrulation proceeds in a flat disc of cells rather than in a ball of cells.

Cleavage in the chick results in a flat, circular layer of cells called a blastodisc ([Figure 43.11](#)). Between the blastodisc and the yolk mass is a fluid-filled space. Some cells from the blastodisc break free and move into this space. These cells come together to form a continuous layer called the [hypoblast](#), which will later contribute to extraembryonic membranes that will support

and nourish the developing embryo. The overlying cells make up the **epiblast**, from which the embryo will form. Thus the avian blastula is a flattened structure consisting of an upper epiblast and a lower hypoblast, which are joined at the margins of the blastodisc. The blastocoel is the fluid-filled space between the epiblast and hypoblast.

Figure 43.11 Gastrulation in Birds Because their eggs contain a large yolk mass, bird and other reptilian embryos have a flattened blastodisc and display a pattern of gastrulation very different from that of amphibians.

hypoblast The lower tissue portion of the avian blastula which is joined to the epiblast at the margins of the blastodisc.

epiblast The upper or overlying portion of the avian blastula which is joined to the hypoblast at the margins of the blastodisc.

Gastrulation begins with a thickening in the posterior region of the epiblast, caused by the movement of cells toward the midline and then forward along the midline (see [Figure 43.12](#)). The result is a midline ridge called the **primitive streak**. A depression called the primitive groove forms along the length of the primitive streak. The primitive groove functions as the blastopore, and cells migrate through it into the blastocoel to become endoderm and mesoderm.

primitive streak A midline ridge that forms in the avian blastula that will become the blastopore.

In the chick embryo, no archenteron forms, but the endoderm and mesoderm migrate forward to form the gut and other structures. At the anterior end of the primitive groove is a thickening

called [Hensen's node](#), which in reptiles, birds, and mammals is the equivalent of the dorsal lip of the amphibian blastopore. Many signaling molecules that have been identified in the frog organizer are also expressed in Hensen's node. Cells moving into the blastocoel and moving anteriorly from Hensen's node become the notochord and organize the chick embryo in a manner similar to that of the frog embryo.

Hensen's node In avian embryos, a structure at the anterior end of the primitive groove; determines the fates of cells passing over it during gastrulation.

Gastrulation in mammals is similar to avian gastrulation

Mammalian embryos (with the exception of monotremes) derive their nourishment from the maternal circulation, and therefore mammalian eggs do not have large amounts of yolk constraining their cleavage and early development. Nevertheless, mammals evolved from reptilian ancestors, so it is not surprising that mammals, birds, and reptiles share certain patterns of early development. Earlier we described the development of the mammalian inner cell mass (the equivalent of the avian blastodisc) and the outer trophoblast.

As in avian development, in placental mammals the inner cell mass splits into an upper layer called the epiblast and a lower layer called the hypoblast. The embryo forms from the epiblast, while the hypoblast contributes to the extraembryonic membranes that will encase the developing embryo and help form the placenta (see [Figure 43.5](#)). The epiblast also contributes to the extraembryonic membranes; specifically, it splits off an upper layer of cells that will form the amnion. The amnion will grow to surround the developing embryo as a membranous sac filled with amniotic fluid. Gastrulation occurs in the mammalian epiblast just as it does in the avian epiblast. A primitive groove forms, and epiblast cells migrate through the groove to become layers of endoderm and mesoderm. At the top of the groove is the node which is homologous with Hensen's node in birds.

How is bilateral symmetry broken?

Gastrulation results in the anterior-posterior and dorsal-ventral patterning of the embryo, but all of the mechanisms discussed produce bilateral symmetry. At the opening of this chapter we introduced an early mechanism that breaks that symmetry to produce the well-known left-right asymmetries of the body. The heart is on the left; the major lobe of the liver is on the right; the pancreas and spleen are on the left; the appendix is on the right; the major blood vessel leaving the heart, the aorta, bends to the left; the right lung has three lobes and the left lung has two; and so on. At the very beginning of gastrulation, the location where the involution of cells begins in a mammal is marked by a node of cells. The ventral surface of the node has ciliated cells. Some of these cilia are motile and others are not. The motile cilia create a leftward flow of extracellular fluid over the node. The experiments in **Investigating Life: Does the Direction of Nodal Flow Influence the Development of Left-Right Asymmetry in the Mouse Embryo?** investigate whether that directional flow is both necessary and sufficient to initiate signaling processes that break bilateral symmetry of the embryo.

 **Does the Direction of Nodal Flow Influence the Development of Left-Right Asymmetry in the Mouse Embryo?**

experiment

Original Paper: Nonaka, S., H. Shiratori and H. Hamata. 2002. Determination of left-right patterning of the mouse embryo by artificial nodal flow. *Nature* 418: 98–99.

HYPOTHESIS▶ The leftward flow of extracellular fluid created by the beating of nodal primary cilia is the stimulus for breaking bilateral symmetry in organ development the mouse.

METHOD

1. Mount wild-type mouse embryos at different stages of development (presomite and 1, 2, or 3 somites; see Figure 43.13) in a culture medium-filled chamber with their nodal ends pointed upward.
2. Artificially pump culture medium through the chamber either from the left (normal) or from the right (reversed) and at slow or fast flow rates.
3. After 4 days assess the embryos as to the direction of looping (normal or reversed) of their developing heart tubes.

RESULTS

Since there were different numbers of embryos in different conditions, and some embryos did not survive, the data are displayed as percent of the total sample under each condition that showed normal or reversed direction of looping of their heart tubes. For example, in the slow left column there were 16 total embryos: 12 had normal direction of looping and 4 had reversed looping. The graph displays how heart-looping patterns were affected in the presomite stage by the direction of culture-medium flow.

Genotype, stage	Speed and direction of culture-medium flow ^a			
	Fast left	Slow left	Slow right	Fast right
Wild type, presomite	9N, 0R, 10T	12N, 4R, 16T	13N, 3R, 16T	2N, 21R, 24T

^aN = normal heart looping; R = reversed looping; T = total embryos in sample.

CONCLUSIONS▶ When extracellular fluid moved across the node from right to left, the direction of heart-tube looping was normal. If this signal was weak (slow left flow), or if a weak reversed signal was applied (slow right flow), there was a small effect on normal direction of heart-tube looping, but when the reversed signal was strong, the heart-tube looping was in the reversed direction. These results support the conclusion that nodal flow is an important signal in breaking bilateral symmetry in the mouse embryo.

work with the data

The experiment illustrated in the graph was done on presomite embryos—before any somites had formed. Developmental signals usually have a time window of effectiveness given that developmental events are sequential and different events must be coordinated. Is there a time window within which nodal flow determines left-right symmetry in the embryo? To investigate the timing of sensitivity to nodal flow, another experiment was conducted using only fast right flow on early embryos at different stages of development.

Genotype, stage	Results
Wild type, presomite	2N, 21R, 24T
Wild type, 1-somite	9N, 0R, 12T
Wild type, 2-somite	22N, 0R, 22T
Wild type, 3-somite	14N, 0R, 14T

QUESTIONS

1. Plot the data as the percent of responses on the y axis and developmental stage on the x axis.
2. Why did this experiment not include left flow as a stimulus?
3. Do these data provide evidence for a sensitive period for nodal flow determining left-right asymmetry?
4. What do you conclude from the results on the 1-, 2-, and 3-somite wild-type embryos?

A similar **work with the data** exercise may be assigned in **LaunchPad**.

43.3 recap

The cell movements of gastrulation convert the blastula into an embryo with three tissue layers. New contacts between cells set up inductive signaling interactions that determine cell fates. Dorsal lip tissue is the source of organizer cells that induce development of preliminary head, trunk, and tail structures.

learning outcomes

You should be able to:

- Compare and contrast gastrulation in frogs and sea urchins.
 - Explain the experiment that revealed the role of the dorsal lip of the amphibian blastopore in embryonic development.
 - Describe the cell movements that occur during gastrulation in sea urchins and amphibians.
 - Summarize how organizer cells achieve a pattern by appropriately expressing growth factor antagonists.
 - Explain the meaning of necessity and sufficiency in investigating potential inductive signals.
 - Compare gastrulation in reptiles and amphibians.
-

1. The sea urchin blastula develops into a radially symmetrical larva, but the frog blastula develops into a bilateral embryo. How does this difference relate to processes of gastrulation in these two types of animals?
 2. What is meant by satisfying the criteria of necessity and sufficiency, and how did the Spemann-Mangold experiments use these criteria to demonstrate the role of the dorsal lip of the blastopore as the primary embryonic organizer?
 3. How do the cells of the primary organizer induce different structures on the anterior-posterior axis as they migrate from the dorsal lip to the head region of the embryo?
 4. How does gastrulation in reptiles compare with that in amphibians?
-

We have described how the fertilized egg develops into an embryo with three germ layers and how cellular signals trigger different patterns of differentiation. In the next section we will describe how organs and organ systems develop.

43.4

Organs Develop from the Three Germ Layers

Gastrulation produces an embryo with three germ layers that are positioned to influence one another through inductive tissue interactions. During the next phase of development, called **organogenesis**, organs and organ systems develop simultaneously and in coordination with each other. In the chordates (see [Key Concept 32.1](#)), an early process of organogenesis is **neurulation**, the initiation of the nervous system. We will examine neurulation in the amphibian embryo, but it occurs in a similar fashion in reptiles (including birds), and in mammals.

organogenesis The formation of organs and organ systems during development.

neurulation Stage in vertebrate development during which the nervous system begins to form.

focus your learning

The chordamesoderm forms the notochord and initiates neurulation.

Segmented blocks of cells, known as somites, produce cells that develop into the vertebrae, ribs, trunk muscles, and limbs.

Hox genes control differentiation on the anterior-posterior axis of vertebrates.

Genetic and environmental factors can lead to neural tube defects.

The organizer sets the stage for organogenesis

One group of cells that passes over the dorsal lip of the blastopore moves anteriorly and becomes the endodermal lining of the digestive tract. Another group of cells that passes over the dorsal lip on the midline becomes chordamesoderm, so named because it forms a rod of mesoderm—the **notochord**—that extends down the center of the embryo. These cells also have important organizer functions (see [Figure 43.8](#)). The notochord gives structural support to the developing embryo and in vertebrates is replaced by the vertebral column. The organizing capacity of the chordamesoderm enables the overlying ectoderm to become neural ectoderm.

notochord (no' tow kord) [Gk. *notos*: back + *chorde*: string] A flexible rod of gelatinous material serving as a support in the embryos of all chordates and in the adults of tunicates and lancelets.

Neurulation involves the formation of an internal neural tube from an external sheet of cells. The first signs of neurulation are flattening and thickening of the ectoderm overlying the notochord; this thickened area forms the neural plate ([Figure 43.12A](#)). The edges of the neural plate that run in an anterior-posterior direction continue to thicken to form ridges or folds. Between these neural folds, a groove forms and deepens as the folds roll over it to converge on the midline. The folds fuse, forming a cylinder, the **neural tube**, and a continuous overlying layer of epidermal ectoderm ([Figure 43.12 B-D](#)).

Figure 43.12 Neurulation in a Vertebrate (A) At the start of neurulation, the ectoderm of the neural plate (green) is flat. (B) The neural plate invaginates and folds, forming a tube. (C, D) The completely formed neural tube seen (C) in diagrammatic form and (D) in a scanning electron micrograph of a chick embryo.

neural tube An early stage in the development of the vertebrate nervous system consisting of a hollow tube created by two opposing folds of the dorsal ectoderm along the anterior–posterior body axis.

Cells from the most lateral portions of the neural plate do not become part of the neural tube, but disassociate from it and come to lie between the neural tube and the overlying epidermis. These **neural crest cells** migrate outward to lead the development of the connections between

the central nervous system (brain and spinal cord) and the rest of the body. Neural crest cells give rise to many diverse structures including jaws, skull, face, pigment cells, glands, smooth muscle, and many others.

neural crest cells During vertebrate neurulation, cells that migrate outward from the neural plate and give rise to connections between the central nervous system and the rest of the body.

The neural tube develops bulges at the anterior end, which become the major divisions of the brain; the rest of the tube becomes the spinal cord. In humans, failure of the neural folds to fuse in this posterior region results in spina bifida, a birth defect in which the spinal cord is exposed because the vertebrae do not fuse. If the folds fail to fuse at the anterior end, an infant can develop without a forebrain (a condition called anencephaly). Although several genetic factors can cause these defects, other factors are environmental, including maternal diet. The incidence of neural tube defects in the United States in the early 1900s was as high as 1 in 300 live births; today it is less than 1 in 1,000. A major factor in this improvement has been the inclusion of folic acid (a B vitamin, also known as folate) in the mother's diet. It is essential for pregnant women to ingest sufficient folic acid.

Body segmentation is an early feature of vertebrate development

The vertebrate body plan, like that of arthropods, consists of repeating segments that are modified during development. These segments are most evident as the repeating patterns of vertebrae, ribs, nerves, and muscles along the anterior-posterior axis.

As the neural tube forms, mesodermal tissues gather along the sides of the notochord to form separate, segmented blocks of cells called **somites** (Figure 43.13). Somites produce cells that will become the vertebrae, ribs, muscles of the trunk, and limbs.

somite (so' might) One of the segments into which an embryo becomes divided longitudinally, leading to the eventual segmentation of the animal as illustrated by the spinal column, ribs, and associated muscles.

Figure 43.13 Developing Body Segmentation (A) Repeating blocks of tissue called somites form on either side of the neural tube. Muscle, cartilage, bone, and the inner layer of the skin form from the somites. **(B)** In this scanning electron micrograph of somite formation in a chick embryo, the overlying ectoderm has been removed and the neural tube and somites are seen from above.

Nerves that connect the brain and spinal cord with tissues and organs throughout the body are also arranged segmentally. The somites help guide the organization of these peripheral nerves, but the nerves are not of mesodermal origin. As you saw above, when the neural tube fuses, the neural crest cells break loose and migrate inward between the epidermis and the somites and through the somites. These neural crest cells have diverse fates, including the development of peripheral nerves.

As development progresses, the different segments of the body change. Regions of the spinal cord differ, regions of the vertebral column differ in that some vertebrae grow ribs of various sizes and others do not, forelegs arise in the anterior part of the embryo, and hind legs arise in the posterior region.

Hox genes control differentiation along the anterior-posterior axis

How is mesoderm in the anterior part of a mouse embryo programmed to produce forelegs rather than hind legs? In [Key Concept 19.4](#), you saw how homeotic genes control body segmentation in *Drosophila*. You also learned that all homeotic genes contain a DNA sequence called the [homeobox](#). In vertebrates, the homeotic genes that control differentiation along the anterior-posterior body axis are called [Hox genes](#) (see [Key Concept 19.3](#)).

homeobox 180-base-pair segment of DNA found in certain homeotic genes. A specific sequence within the homeobox—the homeodomain—regulates the expression of other genes and through this regulation controls large-scale developmental processes. (See homeotic genes.)

Hox genes Conserved homeotic genes found in vertebrates, *Drosophila*, and other animal groups. Hox genes contain the homeobox and specify pattern and axis formation in these animals.

In mammals, four Hox gene complexes reside on different chromosomes in clusters of about ten genes each. Remarkably, the temporal and spatial expression of these genes generally follows the same pattern as their linear order on their chromosome. That is, the Hox genes closest to the 3' end of each gene complex are expressed first and in the anterior of the embryo. The Hox genes at the 5' end of the gene complex are expressed later and in a more posterior part of the embryo. As a result, different segments of the embryo receive different combinations of Hox gene products, which serve as transcription factors ([Figure 43.14](#) ; see also [Figure 19.15](#)).

Figure 43.14 Hox Genes Control Body Segmentation

Whereas Hox genes give cells information about their position on the anterior-posterior body axis, other genes provide information about their dorsal-ventral position. Tissues in each segment of the body differentiate according to their dorsal-ventral location. The notochord provides many of these signals.

After body segmentation develops, the formation of organs and organ systems progresses rapidly. The development of an organ involves extensive inductive interactions. An example is the ability of the chordamesoderm to induce overlying ectoderm to become neural ectoderm, and form the neural tube (see [Figure 43.12](#)). These inductive interactions are a current focus of study for developmental biologists.

43.4 recap

Gastrulation sets up tissue interactions that initiate organogenesis. Neurulation is initiated by organizer mesoderm that forms the notochord. Neurulation results in the formation of the central nervous system, and associated neural crest cells form the peripheral nerves. Suites of Hox genes are expressed sequentially in vertebrates, but in overlapping patterns providing a variety of signaling molecule patterns that govern differentiation on the anterior-posterior axis.

learning outcomes

You should be able to:

- Describe how nervous system development begins with neurulation.

- Describe the formation of somites and their role in development.
 - Explain how genetic and environmental factors can influence neural tube formation.
 - Explain how a limited number of Hox genes can organize complex anterior-posterior patterning of the vertebrate embryo.
-

1. How does the ectoderm overlying the notochord respond to chordamesoderm signals to form a neural tube as well as neural crest cells?
2. What might be a consequence of a failure in somite formation in the embryo?
3. How do Hox genes generate a diversity of signals sufficient to control differentiation of tissues and organs on the anterior-posterior axis?

You have seen how the basic structure of the developing embryo arises, through the establishment of the anterior-posterior and dorsal-ventral axes, the formation of the neural tube, and the emergence of a segmented body plan. In the next section we will examine the developmental events that result in the formation of structures that support the developing embryo: the extraembryonic membranes and the placenta.

43.5 Extraembryonic Membranes Nurture Avian and Mammalian Embryos

There is more to a developing reptile or mammal than the embryo itself. The embryos of these vertebrates are surrounded by several [extraembryonic membranes](#) that originate from the embryo but are not part of it. Extraembryonic membranes function in nutrition, gas exchange, and waste removal. In mammals they interact with tissues of the mother to form the placenta. The evolutionary relationships between the extraembryonic membranes of birds and mammals were discussed in [Key Concept 32.4](#).

extraembryonic membranes Four membranes that support but are not part of the developing embryos of reptiles, birds, and mammals, defining these groups phylogenetically as amniotes. (See amnion, allantois, chorion, yolk sac.)

focus your learning

The four extraembryonic membranes in birds are the yolk sac, the allantoic membrane, the amnion, and the chorion.

The placenta forms from the embryonic chorion and tissues of maternal uterine wall.

During the first trimester, the embryo is most sensitive to environmental effects.

Birds develop four extraembryonic membranes

The chicken provides a good example of how extraembryonic membranes form from the germ layers created during gastrulation. In the chick, four membranes form—the [yolk sac](#), the [allantoic membrane](#), the amnion, and the chorion. The yolk sac is the first to form, and it does so by extension of the hypoblast layer along with some adjacent mesoderm. The yolk sac grows to enclose the entire body of yolk in the egg ([Figure 43.15](#)). It constricts at the top to create a tube that is continuous with the gut of the embryo. However, yolk does not pass through this tube. Yolk is digested by the cells of the yolk sac, and the nutrients are transported to the embryo through blood vessels that form from mesoderm and line the outer surface of the yolk sac. The allantoic membrane is also an outgrowth of the extraembryonic endoderm plus adjacent mesoderm. It forms the [allantois](#), a sac for storage of metabolic wastes.

yolk sac In reptiles, birds, and mammals, the extraembryonic membrane that forms from the endoderm of the hypoblast; it encloses and digests the yolk.

allantoic membrane In animal development, an outgrowth of extraembryonic endoderm plus adjacent mesoderm that forms the allantois, a saclike structure that stores metabolic wastes produced by the embryo.

allantois (al' lun toh is) [Gk. *allant*: sausage] An extraembryonic membrane enclosing a sausage-shaped sac that stores the embryo's nitrogenous wastes.

5-Day chick embryo

The first **extraembryonic membrane** is the **yolk sac**, which is forming in the 5-day embryo.

The mesoderm and ectoderm extend beyond the embryo to form the **chorion** and the **amnion**.

9-Day chick embryo

The mesodermal and ectodermal layers fuse below the yolk so that the chorion lines the shell.

Mesodermal and endodermal tissues form the **allantois**, a sac for metabolic wastes.

Figure 43.15 The Extraembryonic Membranes In birds (and other reptiles) and

mammals, the embryo constructs four extraembryonic membranes. In birds, the yolk sac encloses the yolk, and the amnion and chorion enclose the embryo. Fluids secreted by the amnion fill the amniotic cavity, providing an aqueous environment for the embryo. The chorion, along with the allantoic membrane, mediates gas exchange between the embryo and its environment. The allantois stores the embryo's waste products. (See also [Figure 32.19](#).)

Activity 43.1 Extraembryonic Membranes www.Life11e.com/ac43.1

Ectoderm and mesoderm combine and extend beyond the limits of the embryo to form the other extraembryonic membranes. Two layers of cells extend all along the inside of the eggshell, both over the embryo and below the yolk sac. Where they meet, they fuse, forming two membranes, the inner **amnion** and the outer **chorion**. The amnion surrounds the embryo, forming the amniotic cavity. The amnion secretes fluid into the cavity, providing a protective environment for the embryo. The outer membrane, the chorion, forms a continuous membrane just under the eggshell (see [Figure 43.16](#)) that limits water loss from the egg. The exchange of O₂ and CO₂ between the embryo and the environment requires diffusion of those gases across the chorion and the allantois.

amnion (am' nee on) The fluid-filled sac within which the embryos of reptiles (including birds) and mammals develop.

chorion (kor' ee on) [Gk. *khōrion*: afterbirth] The outermost of the membranes protecting mammal, bird, and reptile embryos; in mammals it forms part of the placenta.

The mammalian placenta forms from extraembryonic membranes

In placental mammals, the first extraembryonic membrane to form is the trophoblast (see [Figures 43.4C](#) and [43.5](#)). When the blastocyst reaches the uterus and hatches from its encapsulating zona pellucida, trophoblast cells interact directly with the endometrium. Adhesion molecules expressed on the surfaces of these cells attach them to the uterine wall. By secreting proteolytic enzymes, the trophoblast burrows into the endometrium, beginning the process of implantation. Eventually the entire trophoblast is within the wall of the uterus. The trophoblast cells send out numerous projections, or villi, to increase the surface area of contact with maternal blood.

Meanwhile, the hypoblast cells proliferate to form what in the bird would be the yolk sac. But there is virtually no yolk in eggs of placental mammals; instead the yolk sac contributes mesodermal tissues that interact with trophoblast tissues to form the chorion. The chorion, along with tissues of the uterine wall, produces the **placenta**, the organ that exchanges nutrients, respiratory gases, and metabolic wastes between the mother and the embryo ([Figure 43.16](#)).

placenta (pla sen' ta) The organ in female mammals that provides for the nourishment of the fetus and elimination of the fetal waste products.

Figure 43.16 The Mammalian Placenta In humans and most other mammals, nutrients and wastes are exchanged between maternal and fetal blood in the placenta, which forms from the chorion and tissues of the uterine wall. The embryo is attached to the placenta by the umbilical cord. Embryonic blood vessels invade the placental tissue to form fingerlike chorionic villi. Maternal blood flows into the spaces surrounding the villi, and placental blood flows through the villi so nutrients and respiratory gases can be exchanged between the maternal and fetal blood.

At the same time the yolk sac is forming from the hypoblast, the epiblast produces the amnion, which grows to enclose the entire embryo in a fluid-filled amniotic cavity. The rupturing of the amnion and chorion and the loss of **amniotic fluid** (the “water breaks”) herald onset of labor in humans.

amniotic fluid The fluid in the amniotic sac that contains mammalian and reptilian embryos.

An allantois also develops in mammals, but its importance depends on how well nitrogenous wastes can be removed by the blood vessels of the placenta. The human allantoic sac is small because the human placenta deals effectively with the fetal nitrogenous wastes. In contrast, the pig placenta is less effective at clearing nitrogenous wastes from the fetus, so the pig’s allantoic sac is large. In humans and other placental mammals, allantoic tissues contribute to the formation of the umbilical cord, by which the embryo is attached to the chorionic placenta (see [Figure 32.19B](#)). It is through the blood vessels of the umbilical cord that nutrients and oxygen from the mother reach the developing fetus, and wastes, including carbon dioxide and urea, are removed.

Human gestation is divided into trimesters

In humans, **gestation**, or pregnancy, lasts about 266 days, or 9 months. Gestation is shorter in smaller mammals (21 days in mice) and longer in larger mammals (600 days in elephants). The events of human gestation (**Figure 43.17**) can be divided into three **trimesters** of roughly 3 months each. The first trimester (see **Figure 43.17A**) is a time of rapid cell division and tissue differentiation. Because signal transduction cascades that determine sequences of developmental processes are in their early stages, the first trimester is the period when the embryo is most sensitive to damage from radiation, drugs, chemicals, and pathogens that can cause birth defects. An embryo can be damaged before the mother even realizes she is pregnant. A classic case is that of thalidomide, a drug widely prescribed in Europe in the late 1950s to treat nausea. Women who took this drug in the fourth and fifth weeks of pregnancy, when the embryo's limbs are beginning to form, gave birth to children with missing or severely malformed arms and legs.

gestation (jes tay' shun) [L. *gestare*: to bear] The period during which the embryo of a mammal develops within the uterus. Also known as pregnancy.

trimesters The three stages of human pregnancy, approximately 3 months each in length.

(A) First trimester

4 Weeks

Actual length ~0.4 cm (4 mm)

8 Weeks

Actual length ~3 cm

(B) Second trimester

4 Months

Actual length ~10 cm

(C) Third trimester

9 Months

Actual length ~40 cm

Figure 43.17 Stages of Human Development (A) At 4 weeks, most of the embryo's organ systems have been formed and the heart is beating. The body structures of this 8-week-old embryo are forming rapidly. **(B)** At 4 months, the fetus has fully formed

limbs with fingers and toes and moves freely within the amniotic cavity. **(C)** This fetus is well along in its ninth month. Soon its lungs will be mature enough to trigger the onset of contractions and birth.

During the second trimester the fetus grows rapidly; its limbs elongate, and its fingers, toes, and facial features become well formed (see [Figure 43.17B](#)). Eyebrows and fingernails grow, and the fetus's nervous system develops rapidly. Fetal movements are first felt by the mother early in the second trimester and become progressively stronger and more coordinated.

The fetus grows rapidly during the third trimester. As this final stage approaches its end (see [Figure 43.17C](#)), the internal organs mature. The digestive system begins to function, the liver stores glycogen, the kidneys produce urine, and the brain undergoes cycles of sleep and waking. A human infant is born when the last of its critical organs—the lungs—mature.

Although the first—trimester embryo is the most susceptible to adverse effects of drugs, chemicals, and diseases, the potential for serious effects from exposure to environmental factors exists throughout pregnancy. Protein malnutrition and exposure to alcohol and cigarette smoke are examples of factors that can result in low birth weight, mental retardation, and other developmental complications.

43.5 recap

The extraembryonic membranes of reptiles and mammals sustain the growing embryo. In reptiles these membranes surround the embryo within the shelled egg. In mammals the extraembryonic membranes form the placenta, an organ that exchanges nutrients, respiratory gases, and metabolic wastes between the mother and the embryo. Human gestation lasts 9 months. At the end of the first trimester, the fetus is very small but most of its organs have begun to form. In the second trimester, limbs elongate and the fetus moves. By the end of the third trimester, most organs have begun to function.

learning outcomes

You should be able to:

- Describe the formation of the yolk sac, amnion, chorion, and allantois, using the chick as an example.
- Summarize how the placenta forms.
- Explain why a first-trimester embryo is particularly sensitive to environmental risks for birth defects.

1. Which germ layers participate in the development of the chick's yolk sac, allantois, chorion, and amnion?
2. What is the origin of the placenta in mammalian development?
3. Why is a first-trimester embryo particularly sensitive to environmental risks?

 investigatinglife

How does the embryo know left from right?

At the beginning of gastrulation in the mammal when midline cells of the epiblast begin to move inward to create the primitive groove, a region called the node forms at the anterior end of the groove. Motile cilia at the node create a flow of extracellular fluid across the node. Non-motile nodal cilia are believed to sense the direction of fluid flow across the node. There are two hypotheses about how these cilia function, one chemical and the other mechanical. Both sensory mechanisms are used by cilia elsewhere in the body. In the nose, cilia of the olfactory cells sense chemicals. In the ear, cilia are bent by sound waves, which stimulates ion channels to open. The leftward flow of fluid across the node imposes mechanical forces on the nonmotile cilia that differ on the two sides of the node. Other research, however, supports the possibility of chemical signaling. Research on the mouse node shows that the beating of the cilia causes proteins of a certain size range to form a concentration gradient across the node. More important, it was discovered that nodal cells secrete small vesicles that are swept to the left side of the node by the flow and burst when they contact the nonmotile cilia of surrounding cells. The contents of these vesicles could be the chemical signals that initiate left-right asymmetry in gene expression and development.

Future directions

A major player in the determination of left-right asymmetry is the primary cilium of cells in the node that forms during gastrulation. However, just about every cell in the body has a primary cilium. Up until fairly recently the primary cilia were thought to be vestigial structures or simply organelles to sequester the centriole and thereby inhibit cell division. We now know that the primary cilia of cells function widely in mechanisms of cell signaling and in transduction of physical and chemical stimuli. Just about every organ in the body uses primary cilia for essential functions. Primary cilia have been implicated in many medical conditions such as cancer, kidney disease, obesity, blindness, and developmental disorders. In the near future we will be seeing lots of new discoveries about the functions of primary cilia.

▶ 43.1 Fertilization Activates Development

- The sperm and the egg contribute differentially to the zygote. The sperm contributes a haploid nucleus and, in most species, a centriole. The egg contributes a haploid nucleus, nutrients, ribosomes, mitochondria, mRNAs, and proteins.
- In amphibians, the cytoplasmic contents of the unfertilized egg are not distributed homogeneously, and they are rearranged after fertilization to set up the major axes of the future embryo. The nutrient molecules are generally found in the [vegetal hemisphere](#), whereas the nucleus is found in the animal hemisphere. **Review** [Figures 43.1](#), [43.2](#)

vegetal hemisphere The lower portion of some animal eggs, zygotes, and embryos, in which the dense nutrient yolk settles. The vegetal pole is to the very bottom of the egg or embryo. (Contrast with animal hemisphere.)

▶ 43.2 Mitosis Divides Up the Early Embryo

- The protein (β -catenin) activates a signaling cascade that induces the primary embryonic organizer and sets up the anterior-posterior body axis. **Review** [Figures 43.2](#)
- [Cleavage](#) is a period of rapid cell division. Except in mammals, little if any gene expression occurs during cleavage. Cleavage can be complete or incomplete, and the pattern of cell divisions depends on the orientation of the mitotic spindles. The result of cleavage is a ball or mass of cells called a **blastula**. **Review** [Figures 43.3](#)

cleavage The first few cell divisions of an animal zygote. (See also complete cleavage, incomplete cleavage.)

- Early cell divisions in mammals are unique in being slow and allowing for gene expression early in the process. These cell divisions produce a [blastocyst](#) composed of an [inner cell mass](#) that becomes the embryo and an outer cell mass that develops as the [trophoblast](#). At the time of [implantation](#), the trophoblast secretes molecules that help the blastocyst implant in the uterine wall. **Review** [Figures 43.4](#), [43.5](#)

blastocyst (blass' toe cist) An early embryo formed by the first divisions of the fertilized egg (zygote). In mammals, a hollow ball of cells.

inner cell mass Derived from the mammalian blastula (blastocyst), the inner cell mass that will give rise to the yolk sac (via hypoblast) and embryo (via epiblast).

trophoblast [Gk *trophes*: nourishment + *blastos*: sprout] At the 32-cell stage of mammalian development, the outer group of cells that will become part of the placenta and thus nourish the growing embryo. (Contrast with inner cell mass.)

implantation The process by which the early mammalian embryo becomes attached to and embedded in the lining of the uterus.

- A **fate map** can be created by labeling specific [blastomeres](#) and observing what tissues and organs are formed by their progeny later in development. **Review Figures 43.6**

blastomere Any of the cells produced by the early divisions of a fertilized animal egg.

- Some species undergo [mosaic development](#), in which the fate of each cell is determined during early divisions. Other species, including vertebrates, undergo [regulative development](#), in which remaining cells can compensate for cells lost in early cleavages.

mosaic development Pattern of animal embryonic development in which each blastomere contributes a specific part of the adult body. (Contrast with regulative development.)

regulative development A pattern of animal embryonic development in which the fates of the first blastomeres are not absolutely fixed. (Contrast with mosaic development.)

► 43.3 Gastrulation Generates Multiple Tissue Layers

- [Gastrulation](#) involves massive cell movements that produce three [germ layers](#) and place cells from various regions of the blastula into new associations with one another. Review [Figure 43.7](#), [Animation 43.1](#)

gastrulation Development of a blastula into a gastrula. In embryonic development, the process by which a blastula is transformed by massive movements of cells into a gastrula, an embryo with three germ layers and distinct body axes.

germ layers The three embryonic layers formed during gastrulation (ectoderm, mesoderm, and endoderm). Also called cell layers or tissue layers.

- The initial step of sea urchin and amphibian gastrulation is inward movement of certain blastomeres. The site of inward movement becomes the [blastopore](#). Cells that move into the blastula become the [endoderm](#) and [mesoderm](#); cells remaining on the outside become the [ectoderm](#). Cytoplasmic factors in the vegetal pole cells are essential to initiate development. Review [Figure 43.7](#), **Focus: Key Figure 43.8**

blastula (blass' chu luh) An early stage of the animal embryo; in many species, a hollow sphere of cells surrounding a central cavity, the blastocoel. (Contrast with blastodisc.)

endoderm [Gk. *endo*: within + *derma*: skin] The innermost of the three embryonic germ layers delineated during gastrulation. Gives rise to the digestive and respiratory tracts and structures associated with them.

mesoderm [Gk. *mesos*: middle + *derma*: skin] The middle of the three embryonic germ layers first delineated during gastrulation. Gives rise to the skeleton, circulatory system, muscles, excretory system, and most of the reproductive system.

ectoderm [Gk. *ektos*: outside + *derma*: skin] The outermost of the three embryonic germ layers first delineated during gastrulation. Gives rise to the skin, sense organs, and nervous system.

- The [dorsal lip](#) of the amphibian blastopore is a critical site for cell determination. It has been called the [primary embryonic organizer](#), or [organizer](#), because it induces determination in cells that pass over it during gastrulation. **Review Figures 43.8-43.10, Animation 43.2**

dorsal lip In amphibian embryos, the dorsal segment of the blastopore. Also called the organizer, this region directs the development of nearby embryonic regions.

primary embryonic organizer See organizer.

organizer Region of the early amphibian embryo that directs early embryonic development. Also known as the primary embryonic organizer.

- Gastrulation in reptiles, including birds, differs from that in sea urchins and frogs because the large amount of yolk causes the blastula to form a flattened disc of cells. **Review Figures 43.11**
- Although their eggs have no yolk, placental mammals have a pattern of gastrulation similar to that of reptiles and birds.
- The direction of extracellular fluid flow over the ventral surface of the node breaks bilateral symmetry in the mammalian gastrula. **Review Investigating Life: Does the Direction of Nodal Flow Influence the Development of Left-Right Asymmetry in the Mouse Embryo?**

▶ 43.4 Organs Develop from the Three Germ Layers

- Gastrulation is followed by [organogenesis](#), the process where tissues interact to form organs and organ systems.

organogenesis The formation of organs and organ systems during development.

- In the formation of the vertebrate nervous system, one group of cells that migrates over the blastopore lip is determined to become the notochord. The notochord organizes the overlying ectoderm to thicken, form parallel ridges, and fold in on itself to form a [neural tube](#) below the epidermal ectoderm. The nervous system develops from this neural tube. **Review Figures 43.12**

neural tube An early stage in the development of the vertebrate nervous system consisting of a hollow tube created by two opposing folds of the dorsal ectoderm along the anterior–posterior body axis.

- The notochord and [neural crest cells](#) participate in the segmental organization of mesoderm into structures called [somites](#) along the body axis. Rudimentary organs and organ systems form during these stages. **Review Figures 43.13**

neural crest cells During vertebrate neurulation, cells that migrate outward from the neural plate and give rise to connections between the central nervous system and the rest of the body.

somite (so' might) One of the segments into which an embryo becomes divided longitudinally, leading to the eventual segmentation of the animal as illustrated by the spinal column, ribs, and associated muscles.

- In vertebrates, [Hox genes](#) determine the pattern of anterior–posterior differentiation along the body axis. Other genes, such as ***sonic hedgehog***, contribute to dorsal-ventral differentiation. **Review Figures 43.14**

Hox genes Conserved homeotic genes found in vertebrates, *Drosophila*, and other animal

groups. Hox genes contain the homeobox and specify pattern and axis formation in these animals.

▶ 43.5 Extraembryonic Membranes Nurture Avian and Mammalian Embryos

- The embryos of reptiles and mammals are protected and nurtured by four [extraembryonic membranes](#). In reptiles the [yolk sac](#) surrounds the yolk and provides nutrients to the embryo, the [chorion](#) lines the eggshell and participates in gas exchange, the [amnion](#) surrounds the embryo and encloses it in an aqueous environment, and the [allantois](#) stores metabolic wastes. Review [Figure 43.15](#), [Activity 43.1](#)

extraembryonic membranes Four membranes that support but are not part of the developing embryos of reptiles, birds, and mammals, defining these groups phylogenetically as amniotes. (See amnion, allantois, chorion, yolk sac.)

yolk sac In reptiles, birds, and mammals, the extraembryonic membrane that forms from the endoderm of the hypoblast; it encloses and digests the yolk.

chorion (kor' ee on) [Gk. *khorion*: afterbirth] The outermost of the membranes protecting mammal, bird, and reptile embryos; in mammals it forms part of the placenta.

amnion (am' nee on) The fluid-filled sac within which the embryos of reptiles (including birds) and mammals develop.

allantois (al' lun toh is) [Gk. *allant*: sausage] An extraembryonic membrane enclosing a sausage-shaped sac that stores the embryo's nitrogenous wastes.

- In mammals the chorion and the trophoblast cells interact with the maternal uterus to form a [placenta](#), which provides the embryo with nutrients and gas exchange. The amnion encloses the embryo in an aqueous environment. Review [Figures 43.16](#)

placenta (pla sen' ta) The organ in female mammals that provides for the nourishment of the fetus and elimination of the fetal waste products.

- Human pregnancy, or [gestation](#), lasts 9 months. The embryo forms in the first **trimester**; during this time, it is most vulnerable to environmental factors that can lead to birth defects. During the second and third trimesters the fetus grows, external features form, and the organ systems mature. Review [Figures 43.17](#)

gestation (jes tay' shun) [L. *gestare*: to bear] The period during which the embryo of a mammal develops within the uterus. Also known as pregnancy.

Go to **LearningCurve** (in **LaunchPad**) for dynamic quizzing that helps you solidify your understanding of this chapter. **LearningCurve** adapts to your responses, giving you the practice you need to master each key concept.

► Apply What You've Learned

Review

- 3.1 Cell movements during gastrulation result in three germ layers and new tissue interactions.
- 3.3 Inductive tissue interactions can suppress as well as activate.
- 3.4 Segmented blocks of cells, known as somites, produce cells that develop into the vertebrae, ribs, trunk muscles, and limbs.
- 3.4 Genetic and environmental factors can lead to neural tube defects.
- 3.5 During the first trimester, the embryo is most sensitive to environmental effects.

Original Paper: Finnell, R. H., J. D. Waes, J. D. Eudy and T. H. Rosen-quist. 2002. Molecular basis of environmentally induced birth defects. *Annual Review of Pharmacology and Toxicology* 42: 181–208.

Both genetic and environmental factors—alone or acting together—can affect the incidence of birth defects in humans. Chemicals in the environment sometimes mimic or interfere with signals involved in inductive tissue interactions, with detrimental results for fetal development. The table below shows the effects of some of these agents.

Chemical/agent Effects on fetus		Comments
Folic acid	Deficiency increases the risk of neural tube defects.	Genetic variants at folate receptor alpha affect the risk of neural tube defects.
Vitamin A	Excess increases mesenchyme defects. Deficiency increases ectoderm defects.	Vitamin A is not synthesized by humans; it must be acquired from the diet.
Valproic acid	Exposure increases the risk of neural tube and other neural defects, craniofacial abnormalities, and skeletal defects.	Valproic acid is used to treat bipolar disorder and epilepsy. It appears to act by impeding the cell cycle during G1 phase.

Questions

1. An infant has various bone, cardiovascular, and muscular system defects. Is this consistent with a vitamin A deficiency? Explain your answer.
2. Suggest a reasonable hypothesis for why vitamin A has different effects on ectoderm-derived tissues than on mesoderm-derived tissues.
3. Suppose there is a genetic variant that causes faster progression through G1 phase of the cell cycle. Would you expect individuals with this variant to be more susceptible or less susceptible to valproic acid during early development?
4. A woman takes valproic acid before she realizes she is pregnant. Would supplements of folic acid be beneficial for this woman's pregnancy? Explain your answer. Why would effects of valproic acid occur so early in the pregnancy?
5. Folate receptor alpha is a protein that is involved in bringing the biologically active form of folic acid into cells. Explain how variants of this protein could affect the frequency of neural tube defects during pregnancy.

flashcards, and additional resources and assignments. ◀

***connect the concepts** As described in [Key Concept 19.2](#), cytoplasmic determinants are regulatory substances that are distributed unequally in the egg cytoplasm and that influence polarity and cell fate during embryogenesis.

Balancing the Brain

Your brain enables you to learn the material in this chapter—to read the words, understand the illustrations, and store information to allow you to answer questions. You must study to master this chapter, but if you do you will learn how the brain receives and processes information.

Imagine what it would be like if you could not learn any of this material—no matter how much you poured over the book. This is the situation faced by individuals with a condition known as Down syndrome, which affects 1 out of every 700 children born in the United States.

Individuals with Down syndrome are born with three copies of most of chromosome 21, one of the smallest of the human chromosomes (containing about 225 confirmed genes). Having an extra copy of these genes causes numerous developmental and functional problems, including learning disability.

Can we understand the cause of this disability and perhaps find a way to remedy it? One productive way of investigating the causes and possible treatments for a human disease or deficit is to develop an animal model. Through genetic engineering, researchers created a “Down syndrome mouse” that has most of the same genes triplicated as those in humans with Down syndrome. These mice cannot perform in mouse memory tests as normal mice do. The mouse Down syndrome model revealed that excess inhibition in the brain causes the learning disability. What is meant by “excess inhibition in the brain”? We tend to think mostly about the excitatory actions of the brain, likening the brain to a puppet master who pulls the strings that activate the muscles and organs of the body. In fact the brain is more like an orchestra conductor, making some sections louder, some softer, speeding up, slowing down. The brain must constantly maintain a delicate balance of excitation and inhibition, acting on some signals and ignoring others. In the brains of Down syndrome model mice there is consistently too much inhibition. When inhibition is experimentally reduced with certain drugs, the mice are able to learn. Research like this is a first step toward bringing potential therapies for humans into clinical trials in the hope of improving the cognitive functions of individuals with Down syndrome.

Can learning be restored in mouse models of Down syndrome?

44.1 Neurons and Glia Are Unique Cells of Nervous Systems

Nervous systems are informational systems. They encode, process, and store a wide variety of information from the external and internal environments, and they use that information to control and regulate the physiology and behavior of the organism. The nervous systems of all animals can carry out these functions because of the properties of a unique class of cells: nerve cells, or [neurons](#). Vertebrate nervous systems also include another unique class of cells called glial cells or [glia](#).

neuron (noor' on) [Gk. *neuron*: nerve] A nervous system cell that can generate and conduct action potentials along an axon to a synapse with another cell.

glia (glee' uh) [Gk. *glia*: glue] One of the two classes of neural cells (along with neurons, with which glia interact); glia do not typically conduct action potentials. Types of glia include astrocytes, oligodendrocytes, and Schwann cells.

focus your learning

The structure of a neuron defines its functions in receiving, integrating, and communicating information.

Specific types of glial cells have unique roles within the nervous system to support, insulate, and nurture neurons and to affect neuronal signaling.

There are many types of neurons, which vary in size, shape, and function, but they all generate and conduct electric signals. Glia do not generate and conduct electric signals, and there are two major types—macroglia and microglia. [Macroglia](#) support and modulate the functions of neurons. [Microglia](#) are phagocytic cells derived from blood-forming stem cells. Microglia are motile, are activated by foreign matter or damage to neural tissue, and are the first and major immune defense mechanism in the nervous system.

macroglia Non-neuronal cells of the central and peripheral nervous system that provide homeostatic functions for neurons, modulate synaptic connections, provide myelin coverings for axons, and create the blood-brain or blood-spinal cord barrier.

microglia Glial cells that act as macrophages and mediators of inflammatory responses in the central nervous system.

Nervous systems in all but the simplest invertebrates are divided into central and peripheral divisions. The central division includes dense assemblages of neurons that process and store information and generate commands. In lower invertebrates these assemblages of neurons are called ganglia. With increased complexity, some large ganglia of invertebrates are designated as brains. In vertebrates the [central nervous system \(CNS\)](#) includes the brain and spinal cord. The [peripheral nervous system \(PNS\)](#) provides communication between the central division and all of the rest of the body.

central nervous system (CNS) That portion of the nervous system that is the site of most information processing, storage, and retrieval; in vertebrates, the brain and spinal cord. (Contrast with peripheral nervous system.)

peripheral nervous system (PNS) The portion of the nervous system that transmits information to and from the central nervous system, consisting of neurons that extend or reside outside the brain or spinal cord and their supporting cells. (Contrast with central nervous system.)

Vertebrate neurons and macroglia originate in the embryonic neural tube

Neurons and macroglia have a common origin in the neural tube of the early vertebrate embryo (see [Figure 43.14](#)). The neural tube contains rapidly dividing neuronal stem cells. Initially the divisions of these neural stem cells are symmetrical—all of the progeny are stem cells. Eventually, however, the cell divisions become asymmetrical, with one daughter cell remaining a stem cell and the other daughter cell becoming either a neural progenitor cell or a macroglial progenitor cell—a neuroblast or a glioblast. These progenitor cells produce the neurons and glia that together form the various structures of the nervous system.

The structure of neurons reflects their functions

Neurons vary enormously in structure and appearance, but they have a basic structure that includes four regions ([Figure 44.1](#)).

Figure 44.1 A Generalized Neuron The diagram shows the features typical of most neurons. The forms of these features, including the length of the single axon and the density and branching patterns of the dendrites, vary greatly across the many different types of neurons.

- A [cell body](#) contains the nucleus and most of the cell's organelles.

cell body The portion of the neuron that contains the nucleus and gives rise to dendrites and an axon.

- Shrublike projections called [dendrites](#) (Greek *dendron*, “tree”) may extend from the cell body. Dendrites receive information from other neurons or sensory cells and bring it to the cell body.

dendrites [Gk. *dendron*: tree] Branching fibers (processes) of a neuron. Dendrites are usually relatively short compared with the axon, and commonly carry information to the neuronal cell body.

- . In most neurons, one projection—the **axon**—is much longer than the others. Axons carry information from the cell body to target cells.

axon [Gk. *axle*] The process (branching structure) of a neuron that conducts action potentials away from the cell body. (See *also* dendrites.)

- . At the target cell, the axon divides into a spray of fine nerve endings. The tips of these tiny nerve endings have swellings called **axon terminals**.

axon terminal The end portion of an axon, which passes action potentials to another cell. Axon terminals can form synapses and release neurotransmitter.

Neurons have a wide variety of forms that reflect different functionalities (**Figure 44.2**). Neurons with few dendrites receive information from specific and limited sources, whereas neurons with large arrays of dendrites can collect and integrate information from a wide range of sources. Some neurons communicate over very short distances, but others communicate over extremely long distances and therefore have very long axons. For example, axons from neurons in your spinal cord control the muscles in your toes.

Figure 44.2 Neurons Have Many and Varied Forms The morphological differences in neurons from different parts of the mammalian nervous system are related to their specific functional adaptations. The small sample here shows two neuronal types from the human brain (a Purkinje cell and a pyramidal cell) and a sensory neuron from the retina of the human eye.

Q: Which of these neurons is likely to receive a greater number of inputs?

Regardless of form and function, all neurons process and communicate information through changes in the electric potential across their membranes. As in all cells, the electric charge on the inside of the cell membrane of a neuron is slightly negative in comparison with the outside. The electric potential across the cell membranes of neurons can change in response to specific stimuli, and these electric potential changes can travel along the cell membrane. In most neurons, small changes in membrane electric potential generate large, rapidly reversed changes in membrane potential that are called **action potentials (APs)**. Axons conduct APs over long distances.

action potentials (APs) Generated by neurons, these are electrical signals that transmit information via waves of depolarization or hyperpolarization of the cell membrane.

In summary, a neuron receives specific stimuli (e.g., light, sound, pressure, chemicals) that cause changes in the electric potentials across the cell membranes of its dendrites. These electric signals from dendrites spread to and are averaged by the cell body. Changes in the electric potential of the membrane of the cell body at the base of its axon can cause an AP that is conducted along the axon to its terminals. APs can travel at speeds up to 100 meters per second (360 kilometers per hour), making it possible for an individual to sense, process, and act on information very quickly.

What happens when the AP reaches the axon terminals? Axon terminals come extremely close to the membrane of the target cell, which can be another neuron, a muscle cell, or a secretory cell. Structures called **synapses** form at these locations. The synapse transfers the information conveyed by the AP from the presynaptic cell to the postsynaptic cell (see [Figure 44.1](#)).

synapse (sin' aps) [Gk. *syn*: together + *haptein*: to fasten] A specialized type of junction where a neuron meets its target cell (which can be another neuron or some other type of cell) and information in the form of neurotransmitter molecules is exchanged across a synaptic cleft.

Synapses can be either electrical or chemical. Electrical synapses allow the AP to pass directly between two neurons. In vertebrates most synapses are chemical. At chemical synapses a space about 25 nanometers wide (about 1/2000th the width of a human hair) separates the presynaptic and postsynaptic membranes. An AP arriving at an axon terminal causes it to release chemical messenger molecules called **neurotransmitters**. Neurotransmitters diffuse across the synaptic space and bind to receptors on the cell membrane of the postsynaptic (target) cell. The binding of the neurotransmitter to its receptor alters the activity of the postsynaptic neuron. Some neurotransmitter-receptor combinations inhibit activity of the postsynaptic neuron, and other neurotransmitter-receptor combinations excite it. Neurons integrate information by summing excitatory and inhibitory inputs. neurotransmitter to its receptor alters the activity of the postsynaptic neuron. Some neurotransmitter-receptor combinations inhibit activity of the postsynaptic neuron, and other neurotransmitter-receptor combinations excite it. Neurons integrate information by summing excitatory and inhibitory inputs. neurotransmitter to its receptor alters the activity of the postsynaptic neuron. Some neurotransmitter-receptor combinations inhibit activity of the postsynaptic neuron, and other neurotransmitter-receptor combinations excite it. Neurons integrate information by summing excitatory and inhibitory inputs. neurotransmitter to its receptor alters the activity of the postsynaptic neuron. Some neurotransmitter-receptor combinations inhibit activity of the postsynaptic neuron, and other neurotransmitter-receptor combinations excite it. Neurons integrate information by summing excitatory and inhibitory inputs.

neurotransmitter A substance produced in and released by a neuron (the presynaptic cell) that diffuses across a synapse and excites or inhibits another cell (the postsynaptic cell).

Glia are the “silent partners” of neurons

The human brain has at least as many glial cells as neurons. The ratio differs in different brain areas, and in some areas is considerably greater than 1 to 1. A neurobiologist once said that

“flashy neurons get all of the attention, but glial cells do most of the brain’s work and are the cause of many of its diseases.” It has been easier to study the functions of neurons because their APs can be observed. The mostly silent glia are more difficult to study, and therefore we know much less about them. Our knowledge of glia will grow enormously in the years to come.

Like neurons, glia come in several forms and have diverse functions. As mentioned above, microglia are macrophages (see [Figure 41.3](#)) and provide immune defense responses for the nervous system. Macroglia include Schwann cells, oligodendrocytes, and astrocytes. In the brain and spinal cord, [oligodendrocytes](#) wrap around the axons of neurons, covering them with concentric layers of cell membrane. You can think of this wrapping as being insulation, like the insulation on electrical wires. It prevents electric current from leaking out of the axon. Outside the brain and spinal cord, [Schwann cells](#) provide this same function for the peripheral nerves that communicate between the brain and spinal cord and all parts of the body ([Figure 44.3](#)). [Myelin](#) is the wrapping produced by oligodendrocytes and Schwann cells, and it gives many parts of the nervous system a glistening white appearance. Not all axons are myelinated, but those that are conduct APs more rapidly than can axons that are not myelinated, for reasons described in [Key Concept 44.2](#).

oligodendrocyte A type of glial cell that myelinates axons in the central nervous system.

Schwann cell A type of glial cell that myelinates axons in the peripheral nervous system.

myelin (my’ a lin) Concentric layers of plasma membrane that form a sheath around some axons; myelin provides the axon with electrical insulation and increases the rate of transmission of action potentials.

(A) Schwann cells

Figure 44.3 Glial Cells Insulate Axons (A) Schwann cells produce layers of myelin,

a type of cell membrane that provides electrical insulation to the axon. At the intervals between Schwann cells—the nodes of Ranvier—the axon is exposed. Action potentials travel along the axon by “jumping” from node to node, as described in [Key Concept 44.2](#). (B) A myelinated axon, seen in cross section through an electron microscope.

Diseases that affect myelin can be devastating because they impair conduction of APs. The most common of these demyelinating diseases is multiple sclerosis (MS)—literally “multiple scars”—which occurs in about 1 in 700 people in the United States. The cause of MS is not known, but it involves inflammatory autoimmune damage to the myelin in the brain and spinal cord. The symptoms of the disease depend on where in the nervous system the myelin is damaged. Motor impairment is common. An example of a demyelinating disease that attacks myelin outside the brain and spinal cord is Guillain-Barre syndrome, which is usually the result of a severe infection. Environmental factors such as pesticide exposure can also damage myelin. There are no known cures for demyelinating diseases.

The third type of macroglia, [astrocytes](#) (so named because they look like stars), contribute to the [blood-brain barrier](#) that protects the brain from toxic chemicals in the blood. Blood vessels throughout the body are very permeable to many chemicals, including toxic ones, that would reach the brain if this barrier did not exist. Astrocytes help form the blood-brain barrier by surrounding the smallest, most permeable blood vessels in the brain. The barrier is not perfect, however. Because it consists of cell membranes, it is permeable to fat-soluble substances such as anesthetics and alcohol (which explains why these substances have such rapid and marked effects on the nervous system).

astrocyte [Gk. *astron*: star] A type of glial cell that contributes to the blood–brain barrier by surrounding the smallest, most permeable blood vessels in the brain.

blood–brain barrier The selective impermeability of blood vessels in the brain that prevents most chemicals from diffusing from the blood into the brain.

In addition to their role in the blood-brain barrier, astrocytes have several known functions at the synapse:

They can take up neurotransmitter that has been released into the synapse and thereby control communication between the pre-and postsynaptic cells.

They can supply neurons with nutrients. Neurons have no energy reserves, but astrocytes store glycogen that they can break down to supply the neurons with fuel.

They have signaling properties. Even though most astrocytes do not generate APs, they do release neurotransmitters that can alter the activities of neurons.

They aid in the repair and regeneration of neurons.

They make contact with both blood vessels and neurons and can therefore signal changes in the composition of the blood.

Astrocytes play crucial yet poorly understood roles in modulating synapse activity. The projections of a single astrocyte may make contact with more than 100,000 synapses. The contact of the astrocyte with the neuronal components of the synapse is so intimate that it has inspired the concept of the [tripartite synapse](#)—the idea that a synapse includes not only the pre-and postsynaptic neurons but also connections from astrocytes.

tripartite synapse The idea that a synapse includes not only the pre-and postsynaptic

neurons involved but also encompasses many connections with glial cells called astrocytes.

Although astrocytes do not generate APs, they do communicate with each other. They are connected to each other through electrical synapses, and the electric signals traveling across these synapses cause changes in the Ca^{2+} content of the postsynaptic astrocyte. When Ca^{2+} -sensitive dyes are applied to neural tissue, Ca^{2+} waves can be seen traveling through extensive networks of astrocytes. The functions of these Ca^{2+} waves are not understood.

44.1 recap

Nervous systems have two unique types of cells: neurons and glia. There are many types of neurons, but they can all generate and conduct electric signals, and most generate APs. A neuron has four regions: cell body, dendrites, axon, and axon terminals. Neurons communicate with target cells at synapses, which can be chemical or electrical. Although glia do not generate APs, they have a variety of functions, including contributing to the blood-brain barrier, insulating axons, and modulating synaptic activity.

learning outcomes

You should be able to:

- Describe the parts of a neuron and explain their functions.
 - Explain how the functions of axons and dendrites make it possible to communicate information across the synapse.
 - Describe the different functions of glial cells.
-
1. Draw two neurons, including a synapse between them, and label all of the parts. At a chemical synapse, how does a signal from one neuron cross the synaptic space to another neuron?
 2. Explain how a neuron integrates information received from several other neurons.
 3. Explain how astrocytes modulate synaptic activity.

The one feature common to neurons is that they process information in the form of changes in the electric potential across their cell membranes. In the next section we will focus on how electric signals are generated and transmitted by neurons.

44.2 Neurons Generate and Transmit Electric Signals

Various ion pumps create ion concentration gradients across animal cell membranes. For example, Na^+ concentrations are higher outside cells and K^+ concentrations are higher inside. The positive charges of these ions are balanced by negatively charged ions both inside and outside the cell. But, across the cell membrane there is an electric charge difference, with the inside of the cell being negative relative to the outside. This electrical charge is due to the cell membrane being differentially permeable to certain ions. For neurons at rest, their membranes are mostly permeable to K^+ , and that permeability is primarily responsible for the electrical charge across their membranes.

focus your learning

The membrane at rest is close to the equilibrium potential for K^+ due to the selective permeability to K^+ through “leak” channels open at rest.

When gated ion channels are activated by electrical, chemical, or mechanical stimuli, permeability of the membrane to the respective ions changes, resulting in a change in membrane potential.

Potential changes, through both inhibitory and excitatory inputs, are summed and result in the membrane potential deviating from the resting potential.

Rapid activation and inactivation of voltage-gated Na^+ channels are responsible for action potentials.

Action potentials are all-or-none, self-regenerating events that are conducted rapidly and unidirectionally along axons. Myelination of axons results in saltatory conduction, which is faster than conduction in nonmyelinated axons.

Because the concentration of K^+ is higher inside the cell than in the extracellular fluid, K^+ diffuses out of the cell down its concentration gradient. But when K^+ leaks out of the cell, it leaves behind an unbalanced negative electric charge that tends to pull K^+ back into the cell. An equilibrium is reached when the tendency for K^+ to diffuse out is countered by the electric charge pulling K^+ back in. The resulting charge difference across the membrane is called the **membrane potential**, with the inside of the cell negative relative to the outside. Membrane potentials exist in all cells.

membrane potential The difference in electrical charge between the inside and the outside of a cell, caused by a difference in the distribution of ions.

Membrane potentials exist in all cells. In neurons the steady-state membrane potential is called the **resting potential**. Stimuli that cause changes in the permeability of the cell membrane cause local changes in that membrane potential. These local changes can generate the large electrical signals called action potentials (APs) that are conducted along the axons and

convey information about the stimulus that caused the initial small change in membrane potential. The AP is a sudden, large, transient change in membrane potential generated by sudden changes in permeability to Na^+ ions. Before describing the mechanisms of these permeability changes and the resulting APs in detail, a review of some simple concepts of electricity may be useful.

resting potential The membrane potential of a living cell at rest. In cells at rest, the interior is negative to the exterior. (Contrast with action potential.)

Simple electrical concepts underlie neuronal function

Voltage (electric potential difference) is a force that causes electrically charged particles to move between two points. Voltage is to the flow of electrically charged particles as pressure is to the flow of water. If the negative and positive poles of a battery are connected by a wire, an electric current will flow through the wire because there is a voltage difference between the two poles. This flow of electric current can be used to do work, just as a current of water can be used to do work.

voltage A measure of the difference in electrical charge between two points.

In wires, electric current is carried by electrons, but in solutions and across cell membranes, electric current is carried by ions. The major ions that carry electric charges across the cell membranes of neurons are sodium (Na^+), potassium (K^+), calcium (Ca^{2+}), and chloride (Cl^-). Recall that ions with opposite charges attract one another and those with like charges repel one another. How do these basic principles of bioelectricity establish the resting potential of the neuronal cell membrane? And how is the flow of ions through membrane channels turned on and off to generate APs?

Activities of neurons are recorded as changes in membrane potential

We record electrical events in a cell using electrodes. **Figure 44.4** shows how this technique is applied across the cell membrane of a neuron to measure the resting potential, which is usually between -60 and -70 millivolts (mV). The minus sign indicates that the inside of the cell is electrically negative compared with the outside.

Figure 44.4 Measuring the Membrane Potential An electrode can be made from a glass pipette with a very sharp tip filled with a solution that conducts electric charges. If one electrode is placed inside the neuron and another one on the outside of the cell membrane, the difference in voltage across the cell membrane can be measured.

As explained above, the resting potential is largely due to a balance between the tendency of K^+ ions to diffuse down their concentration gradient and the electrical potential that holds them back. This resting potential provides a means for a neuron to respond to stimuli. If some determinant of this balance of forces is altered, the membrane potential will change. The concentration gradient of the different ions inside and outside of the neuron may not change, but if the permeability of the membrane to ions changes, the membrane potential will change. Therefore, any chemical or physical stimulus that changes the permeability of the cell membrane to ions will cause a change in the cell's membrane potential. For example, what would happen to the cell membrane potential if there was a sudden increase in the permeability of the membrane to Na^+ ions. Na^+ ions are more abundant outside the cell than inside. Also, the inside of the resting cell is negatively charged which attracts the positively charged Na^+ ions. Thus, a sudden large increase in permeability of the membrane to Na^+ would cause a change of the membrane potential in the positive direction. If the change in Na^+ permeability were transient, the membrane potential would rapidly return to its resting, negative value. Such a rapid change in membrane potential is an AP.

Animation 44.1 The Resting Membrane Potential www.Life11e.com/a44.1

Ion transporters and channels generate membrane potentials

The cell membranes of neurons, like those of all other cells, are lipid bilayers that are impermeable to ions but contain many protein molecules that serve as ***ion transporters** and ion channels. Ion transporters and channels are responsible for the distribution of charges across the membrane that determine membrane potential.

Ion transporters require energy to move ions against their concentration or electrical gradients and are therefore called ion pumps. A major ion transporter in the cell membranes of neurons (and all other cells) is the **sodium-potassium pump**, so called because it actively expels Na^+ ions from inside the cell, exchanging them for K^+ ions from outside the cell (see [Figure 6.14](#)).

The $\text{Na}^+\text{-K}^+$ pump is also known as sodium-potassium ATPase, a term emphasizing that it is an enzyme complex requiring ATP to do its work. The $\text{Na}^+\text{-K}^+$ pump keeps the concentration of K^+ inside the cell greater than the K^+ concentration of the extracellular fluid, and the concentration of Na^+ inside the cell less than that of the extracellular fluid. The concentration differences established by this active transporter mean that K^+ would diffuse out of the cell and Na^+ would diffuse in if the ions could cross the lipid bilayer. How do these concentration gradients relate to the electrical gradients we discussed above?

Ion channels permit the diffusion of ions across membranes. These channels are water-filled pores formed by proteins that span the lipid bilayer and are generally selective, allowing some types of ions to pass through more easily than others (see [Figure 6.11](#)). Thus there are potassium channels, sodium channels, chloride channels, and calcium channels, and there are different kinds of channels for each ion. Ions can diffuse through these channels in either direction. The direction and magnitude of the net movement of ions through a channel depend on the concentration gradient of that ion type across the cell membrane, as well as on the voltage difference across that membrane. These two motive forces acting on an ion are termed its **electrochemical gradient**. Although the electrochemical gradient drives the movement of ions through channels, that movement is modified by gates that open and close the channels.

electrochemical gradient The concentration gradient of an ion across a membrane plus the voltage difference across that membrane.

Potassium channels are the most common open, or leak, channels in the cell membranes of resting (nonstimulated) neurons. As a consequence, resting neurons are more permeable to K^+ than to any other ion. Thus, open potassium channels are largely responsible for the resting membrane potential. Because the potassium channels make the cell membrane permeable to K^+ , and because the $\text{Na}^+\text{-K}^+$ pump keeps the concentration of K^+ inside the cell much higher than that outside the cell, K^+ tends to diffuse down its electrochemical gradient, out of the cell, through the channels. But, if K^+ ions left the cell they would leave behind unbalanced negative charges, generating an electric potential across the membrane that tends to pull K^+ back into the cell.

The membrane potential at which the net diffusion of K^+ out of the cell ceases (that is, the point at which K^+ diffusion out due to the concentration gradient is balanced by its inward movement due to the negative electric potential) is the **potassium equilibrium potential**, or E_K . The value of E_K can be calculated from the concentrations of K^+ on the two sides of the membrane using the **Nernst equation** ([Figure 44.5A](#)). This equation, developed in the late 1800s, shows that the existence of ion channels in neuronal membranes was hypothesized long before their specific structures and properties were discovered.

potassium equilibrium potential (E_K) The negative membrane potential that balances the tendency for K^+ ions to diffuse out of the cell down its concentration gradient.

Nernst equation A mathematical statement that calculates the potential across a membrane permeable to a single type of ion that differs in concentration on the two sides of the membrane.

1. Measure concentrations of ions inside and outside a neuron.

To measure the concentration of ions in a neuron, the neuron (and its axon) must be big. Squid have giant neurons that control their escape response (see Figure 44.13C). It is possible to sample the cytoplasm of these axons, which are about 1 mm in diameter.

2. Use the Nernst equation to calculate what the membrane potential would be if it were permeable to each of the ions that are differently concentrated on the two sides of the membrane: Na^+ , K^+ , Ca^{2+} , and Cl^- .

The Nernst equation predicts the membrane potential resulting from membrane permeability to a single type of ion that differs in concentration on the two sides of the membrane. The equation is written

$$E_{\text{ion}} = 2.3 \frac{RT}{zF} \log \frac{[\text{ion}]_o}{[\text{ion}]_i}$$

where E is the equilibrium (resting) membrane potential (the voltage across the membrane in mV), R is the universal gas constant, T is the absolute temperature, z is the charge on the ion, and F is the Faraday constant. The subscripts o and i indicate the ion concentrations outside and inside the cell, respectively.

At this point you could just “plug and play,” but do you understand this equation?

A concentration difference of ions across a membrane creates a chemical force that pushes the ions across the membrane by diffusion; however, the resulting unbalanced electric charges will pull the ions back the other way. At equilibrium, the two forces are in balance and there is no net movement of ions across the membrane.

The chemical energy pushing the ions will equal $2.3 RT \log [\text{ion}]_o/[\text{ion}]_i$

The electric energy pulling the ions will equal zEF . So, at equilibrium:

$$zEF = 2.3 RT \log \frac{[\text{ion}]_o}{[\text{ion}]_i}$$

Rearranging the equation to solve for E , we get the Nernst equation:

$$E_{\text{ion}} = 2.3 \frac{RT}{zF} \log \frac{[\text{ion}]_o}{[\text{ion}]_i}$$

We can simplify the equation by picking a temperature—let’s use “room temperature,” or 20°C —and solving for $2.3 RT/F$. At 20°C , $2.3 RT/F$ equals 58. Thus:

$$E_{\text{ion}} = 58/z \log \frac{[\text{ion}]_o}{[\text{ion}]_i}$$

Measuring ion concentrations in squid giant axon cytoplasm and in seawater, then solving the Nernst equation for each ion, we find:

Ion	Ion concentration (mM)		Predicted membrane potential (mV)
	in squid axon	in seawater	
K^+	400	20	-75
Na^+	50	460	+56
Ca^{2+}	0.5	10	+38
Cl^-	50	560	-60

3. Since the measured membrane potential is -66 mV , it is clear that the resting potential of the axon is due to permeability of the membrane to more than just one type of ion.

Figure 44.5A Using the Nernst Equation The Nernst equation calculates membrane potential when only one type of ion can cross a membrane that separates solutions with different concentrations of that ion.

work with the data

Figure 44.5B Equilibrium Membrane Potential: The Goldman Equation

Original Papers: Goldman, D. E. 1943. Potential, impe-dence and rectification in membranes. *Journal of General Physiology* 27: 37-60.

Hodgkin, A. L. and B. Katz. 1949. The effect of sodium ions on the electrical activity of the giant axon of the squid. *Journal of Physiology* 108: 37-77.

[Figure 44.5A](#) presented the Nernst equation, by which the membrane potential for a single ion can be determined. But you also saw (at the end of [Figure 44.5A](#)) that the equilibrium membrane potential is the product of more than one ion. The Goldman equation (frequently called the Goldman, Hodgkin, Katz equation) calculates the equilibrium membrane potential by taking into account all of the ions that can diffuse across a given membrane and the relative permeabilities of the membrane to those ions. The ions involved in mammalian neurons here are K⁺, Na⁺, and Cl⁻, and the Goldman equation is

$$v_m = RT/F \ln \left(\frac{p_K [K^+]_o + P_{Na} [Na^+]_o + P_{Cl} [Cl^-]_i}{p_K [K^+]_i + P_{Na} [Na^+]_i + P_{Cl} [Cl^-]_o} \right)$$

Relative permeabilities (*p*) are expressed as ratios. The mem-brane’s permeability to potassium ions is the highest, so *p_K* =1.0. Then *p_{Na}* = 0.05 and *p_{Cl}* = 0.44. Bracketed elements refer to the inside and outside ion concentrations, as in the Nernst equation.

QUESTION

1. The table gives the intra-and extracellular ion concentrations for a mammalian neuron. Use these values and the Goldman equation to calculate the membrane potential. Refer to [Figure 44.5](#) for a comparison with calculations based on the Nernst equation. (Hint: In redrafting the equation, you can substitute “2.3RT/F log” for “RT/F ln.”)

	Ion concentration (mM)	
	Intracellular	Extracellular
K ⁺	140	5
Na ⁺	10	145
Cl ⁻	20	115

A similar **work with the data** exercise may be assigned in **LaunchPad**.

In the late 1940s, A. L. Hodgkin and A. F. Huxley at the University of Cambridge set out to study the electrical properties of axonal membranes. With the techniques available at that time, the necessary measurements could be made only if you had a very large axon to work with. Such an axon exists in nature—the huge neuron that controls the escape response of squid. Hodgkin and Huxley used electrodes to measure the voltage across the cell membrane of this large axon, as seen in [Figure 44.5](#), and to pass electric current into it to change its membrane potential. They also changed the concentrations of Na⁺ and K⁺ both inside and outside the squid axon and measured the resulting changes in membrane potential. On the basis of their many careful experiments, Hodgkin and Huxley developed virtually all of our basic concepts

about the electrical properties of neurons, and they shared a Nobel Prize in 1963.

The resting potential of a neuron is less negative than the E_K calculated from the Nernst equation. This means that the resting potential is not due solely to leak K^+ channels. The neuronal membrane is slightly permeable to other ions, especially Na^+ and Cl^- , and movements of these ions influence the resting potential. A different equation takes into account (1) all of the ions that can cross the membrane and (2) the relative permeability of the membrane to those ions. This equation, called the **Goldman equation**, predicts the membrane potential more accurately than does the Nernst equation (**Figure 44.5B**).

Goldman equation An equation that calculates membrane potential by taking into consideration the concentration differences of all ions on both sides of the membrane and the relative permeability of the membrane to those ions.

Ion channels and their properties can be studied directly

Because Hodgkin and Huxley were working long before there were laboratory techniques enabling the investigation of ion channels, they could only hypothesize ion channel properties. These hypotheses could not be tested until the late 1970s, when B. Sakmann and E. Neher developed a technique called **patch clamping**, for which they shared the Nobel Prize in 1991. Patch clamping, described in **Figure 44.6**, is widely used by neurobiologists, enabling them to record in real time the tiny electric currents caused by the openings and closings of single ion channels.

patch clamping Technique for isolating a tiny patch of membrane to allow the study of ion movement through a particular channel.

research tools

Figure 44.6 Patch Clamping The patch clamp electrode is a glass micropipette with a polished tip and filled with an electrically conductive solution that has the same composition as extracellular fluids. When this pipette/electrode is positioned against the membrane of a cell and slight suction is applied, a seal forms. If a single ion channel (or a few ion channels) are within the patch of membrane bounded by the seal, the openings and closings of individual channels can be recorded by the electrode. If the pipette is retracted, it can tear the patched membrane away from the cell, and the activities of the ion channels in the patch can continue to be recorded.

Slight suction creates a seal between the pipette tip and a patch of the membrane.

Retracting the pipette removes the membrane patch, often with one or more ion channels in it.

Tracing of ionic current shown on computer screen

The opening and closing of ion channels can be recorded through the pipette.

Gated ion channels alter membrane potential

The ion channels called leak channels are always open, but other ion channels in the cell membranes of neurons behave as if they contain “gates”; they are open under some conditions and closed under other conditions. [Voltage-gated channels](#) open or close in response to a change in the voltage across the cell membrane. [Chemically gated channels](#) open or close depending on the presence or absence of a specific molecule that binds to the channel protein, or to a separate receptor that in turn alters the channel protein. [Mechanically gated channels](#)

open or close in response to mechanical force applied to the cell membrane. Gated channels play important roles in neuronal function.

voltage-gated channel A type of gated channel that opens or closes when a certain voltage exists across the membrane in which it is inserted.

chemically gated channel A type of membrane channel that opens or closes depending on the presence or absence of a specific molecule that binds either to the channel protein itself or to a separate receptor that alters the three-dimensional shape of the channel protein.

mechanically gated channel A molecular channel that opens or closes in response to mechanical force applied to the plasma membrane in which it is inserted.

Openings and closings of gated channels alter the membrane potential. Above, you considered what would happen if the permeability of the membrane to Na^+ suddenly increased. Such a change in local membrane permeability is generated by the opening of Na^+ channels. Na^+ ions would move down their electrochemical gradient until the membrane approaches the equilibrium potential for Na^+ (E_{Na}). Therefore, the inside of the cell becomes less negative. When the inside of a neuron becomes less negative (or more positive) in comparison to its resting condition, its cell membrane is **depo-larized** (Figure 44.7). The opposite change in the membrane potential occurs if gated K^+ channels open. Opening of these channels increases the permeability of the cell membrane to K^+ , and the membrane potential becomes even more negative than when only the leak K^+ channels were open, and it is said to be **hyperpolarized**.

Figure 44.7 Membranes Can Be Depolarized or Hyperpolarized The resting potential is produced mostly by leak K^+ channels with a small contribution from leak Na^+ channels (not shown here). A shift from the resting potential to a less negative membrane potential caused by increased Na^+ permeability is called depolarization. Hyperpolarization occurs when the membrane potential becomes more negative as when the permeability of the membrane to K^+ increases.

The openings and closings of ion channels that result in changes in the voltage across the cell membrane are the basic mechanisms by which neurons respond to stimuli, be they electrical, chemical, or mechanical. How do such local changes in membrane potential get communicated to other parts of the cell?

A local change in membrane potential causes a flow of ions that spreads the change in membrane potential to adjacent regions of the membrane. For example, when Na⁺ channels in an axon open making that region of the axon positive, a rapid flow of ionic electric current in the axoplasm causes a decay in that electrical potential change, and it does not spread very far.

Graded changes in membrane potential can integrate information

The flow of ionic electric current along cell membranes can only extend over a short distance, but it causes a graded change in the local membrane potential. A **graded membrane potential** is a change from the resting potential that is proportional to the magnitude of a stimulus. That stimulus can be chemical or mechanical. Graded potentials are a means of integrating stimuli because the membrane can respond with proportional amounts of depolarization or hyperpolarization to each stimulus, and those changes in membrane potential are summed. In the next chapter you will learn how graded potentials play important roles in sensory systems. However, the spread of graded potentials can only be local and cannot be transmitted down long axons. Therefore axons code information as discrete APs that travel along their membranes. Graded potentials, however, play an important role in the generation of APs.

graded membrane potential Small local change in membrane potential caused by opening or closing of ion channels.

Sudden changes in Na⁺ and K⁺ channels generate action potentials

APs are sudden, transient, large changes in membrane potential. In unmyelinated axons (those not wrapped in myelin by oligodendrocytes or Schwann cells), APs can be conducted at speeds of up to 2 meters per second, but in myelinated axons the conduction velocity can be 100 meters per second. Think of running the 100-meter dash—the world record is slightly under 10 seconds.

If we place the tips of a pair of electrodes on either side of the cell membrane of a resting axon and measure the voltage difference, the reading might be about -60 mV, as you saw in [Figure 44.4](#). If these electrodes are in place when an AP travels down the axon, they register a rapid change in membrane potential, from -60 mV to about +50 mV. The membrane potential then rapidly returns to its resting level of -60 mV ([Figure 44.8](#)).

Figure 44.8 The Course of an Action Potential Action potentials result from rapid changes in voltage-gated Na^+ and K^+ channels.

Animation 44.2 The Action Potential www.Life11e.com/a44.2

The AP is generated by the openings and closings of voltage-gated Na^+ and K^+ channels in the cell membrane of the axon. At the resting potential, most of these channels are closed except for the leak K^+ channels (balloon 1 in [Figure 44.8](#)). A slight depolarization of the cell membrane in this area causes some voltage-gated Na^+ channels to open. Specifically, if a neuron is stimulated sufficiently to cause the membrane of its cell body to depolarize slightly, that graded potential spreads by local current flow to the **axon hillock**, the region of the cell body at the base of the axon (see [Figure 44.1](#)). Voltage-gated Na^+ channels are concentrated in the axon hillock. A slight depolarization of the cell membrane in this area causes some of these voltage-gated channels to open briefly—for less than a millisecond (balloon 2 in [Figure 44.8](#)). When these channels open, the increased Na^+ permeability depolarizes the membrane even more, causing more Na^+ channels to open—a positive feedback effect. When the membrane is depolarized about 5-10 mV above the resting potential, a **threshold** is reached; a large number of sodium channels open (balloon 3 in [Figure 44.8](#)), and the membrane potential becomes positive—an AP. The rising phase of the AP halts abruptly in 1-2 milliseconds, and the

membrane potential rapidly becomes negative once again.

axon hillock The junction between an axon and the neuron's cell body; where action potentials are generated.

threshold The level of depolarization that causes an electrically excitable membrane to fire an action potential.

What causes the axon to return to resting potential? There are two contributing factors: the voltage-gated Na^+ channels close, and voltage-gated K^+ channels open (balloon 4 in [Figure 44.8](#)). Voltage-gated K^+ channels open in response to the same depolarization that triggered the Na^+ channels, but they do so more slowly and they stay open longer, allowing K^+ to carry excess positive charges out of the axon. As a result, the membrane potential returns to a negative value and usually becomes even more negative than the resting potential until the voltage-gated K^+ channels close (balloon 5 in [Figure 44.8](#)).

Another feature of the voltage-gated Na^+ channels is that once they open and close, they have a [refractory period](#) of 1-2 milliseconds during which they cannot open again. This property can be explained by the channels having two gates, an [activation gate](#) and an [inactivation gate](#) (see [Figure 44.8](#)). Under resting conditions, the activation gate is closed and the inactivation gate is open. Depolarization of the membrane to the threshold level causes both gates to change state, but the activation gate responds faster. As a result, the channel is open for a brief time between the opening of the activation gate and the closing of the inactivation gate. Inactivation gates remain closed for 1-2 milliseconds before they spontaneously open again, thus explaining the refractory period. By the time the inactivation gate reopens, the activation gate is closed, and the membrane is poised to generate another AP. Another contribution to the refractory period is the duration of the opening of the voltage-gated K^+ channels, as you saw above. The dip in the membrane potential following an AP is called the [after-hyperpolarization or undershoot](#).

refractory period The time interval after an action potential during which another action potential cannot be elicited from an excitable membrane.

activation gate The property of a voltage-gated Na^+ ion channel that increases its permeability to Na^+ ions when the membrane is depolarized.

inactivation gate The property of a voltage-gated Na^+ ion channel that decreases its permeability to Na^+ when the membrane is depolarized.

after-hyperpolarization A fall in membrane potential below normal resting level following an action potential.

The difference in the concentration of Na^+ across the cell membrane and the negative resting potential constitute the “battery” that drives APs. How rapidly does the battery run down? It might seem that a substantial number of ions would have to cross the membrane for the membrane potential to change from -60 mV to +50 mV and back to -60 mV again. In fact, only a vanishingly small number of Na^+ ions move through the channels during the passage of an active potential. Thus, the effect of a single action potential on the concentration gradients of Na^+ and K^+ is very small, and the sodium-potassium pump can keep the “battery” charged, even when the neuron is generating many APs every second.

Action potentials are conducted along axons without loss of signal

An AP is conducted over long distances with no loss of signal. If we place two pairs of electrodes at two different locations along an axon, we can record an AP at those two locations as it travels along the axon ([Figure 44.9A](#)). The magnitude of the AP does not change between the two recording sites. This constancy is possible because an AP is an *all-or-none*, *self-regenerating event*.

Figure 44.9 Action Potentials Travel along Axons (A) There is no loss of signal as an action potential travels along an axon. (B) When an action potential is stimulated in one region of membrane, ionic current flows to and depolarizes adjacent areas of membrane. (C) The advancing wave of depolarization causes more Na^+ channels to open, and the action potential is generated anew in the next section of membrane. Meanwhile, in the region where the action potential has just fired, the Na^+ channels

are inactivated and the voltage-gated K^+ channels are still open, rendering this section of the axon incapable of generating an action potential. Hence the action potential cannot “back up,” but moves continuously forward, regenerating itself as it goes.

An AP is *all-or-none* because of the interaction between the voltage-gated Na^+ channels and the membrane potential. If the membrane is depolarized slightly, some voltage-gated Na^+ channels open. Some sodium ions cross the cell membrane and depolarize it even more, opening more voltage-gated Na^+ channels, and so on, generating an AP. This positive feedback mechanism ensures that APs always rise to their maximum value.

An AP is *self-regenerating* because it spreads by local current flow to adjacent regions of the cell membrane. The resulting depolarization brings those neighboring areas of membrane to threshold. Therefore, when an AP occurs at one location on an axon, it stimulates the adjacent region of axon to generate an AP, and so on down the length of the axon. Although we say that the AP travels down the axon, what is really happening is that new APs are being created sequentially.

We can use an electrode to stimulate an axon, causing it to depolarize and to fire an AP that is then conducted along the axon. [Figure 44.9B](#) shows the changes in the ion channels in the membrane that are responsible for conducting the AP along the axon without a reduction in amplitude. Normally an AP is propagated in only one direction—away from the cell body. It cannot reverse itself because the voltage-gated Na^+ channels in the region of the membrane it came from are in their refractory period ([Figure 44.9C](#)).

APs are not conducted at the same speed in all axons. They travel faster in large-diameter axons than in small-diameter axons because the resistance to ionic current flow decreases as an axon's diameter gets bigger. They travel faster in myelinated than in nonmyelinated axons because they can move down the axon in short “jumps” as described in the next section ([Figure 44.10](#)). Invertebrates depend on increased axon diameter for fast conduction, but vertebrates mostly depend on myelination of axons to increase conduction velocity.

Figure 44.10 Saltatory Action Potentials Action potentials “jump” from node to node in myelinated axons, allowing faster transmission of information.

Action potentials jump along myelinated axons

In vertebrate nervous systems, increasing the speed of APs by increasing the diameter of axons is not feasible because of the huge number of axons involved. Each of our eyes, for example, has about a million axons connecting it to the brain. These axons conduct APs at about the same speed as does the squid giant axon—about 20 meters per second—yet the diameter of each is 200 times smaller than the squid axon's diameter. Imagine having optic tracts 200 times bigger. A different way of increasing conduction velocity of axons has evolved in vertebrates, and that adaptation is myelination.

When glia wrap around axons, they cover the axons with concentric layers of myelin (see [Figure 44.3](#)). However, they leave regularly spaced gaps called **nodes of Ranvier**, where the axon is not covered (see [Figure 44.10](#)). Underneath the myelin sheaths, there are no Na^+ or K^+ channels, therefore, APs cannot propagate under the myelin sheath. However, an AP firing at a node of Ranvier creates a local electrical field inside the axon that spreads almost instantaneously to the next node of Ranvier. The resulting de-polarization of that node triggers

another AP, and so on down the axon. Thus the APs appear to jump from node to node, and their conduction down the axon is very fast.

node of Ranvier A gap in the myelin sheath covering an axon; the point where the axonal membrane can fire action potentials.

The speed of conduction is increased in these myelin-wrapped axons because electric current flows much faster through the cytoplasm than ion channels can open and close. This form of rapid impulse propagation is called **saltatory conduction** (Latin *saltare*, “to jump”).

saltatory conduction [L. *saltare*: to jump] The rapid conduction of action potentials in myelinated axons; so called because action potentials appear to “jump” between nodes of Ranvier along the axon.

44.2 recap

Neurons have membrane potentials due to ion concentration differences across their membranes and the different permeabilities of the membrane to those ions created by ion channels. Leak channels generate the resting potential, and opening and closing of gated channels can create graded changes in membrane potentials depending on how many of which channel types open or close. Voltage-gated channels have threshold potentials for opening. If some voltage-gated Na^+ channels open, they create a local depolarization that brings other Na^+ channels to threshold—a positive feedback mechanism that generates APs. Sudden closure of Na^+ channels and the opening of K^+ channels terminate the AP. APs are rapid, all-or-none changes in membrane potential that are conducted along axons from the cell body to the axon terminals. In myelinated axons, APs jump between nodes of Ranvier and conduction is more rapid than in nonmyelinated axons.

learning outcomes

You should be able to:

- Demonstrate an understanding of how a membrane potential can be calculated based on intra-and extracellular ion concentration differences and relative permeabilities of the membrane to those ions.
- Describe how graded membrane potentials enable a neuron to integrate various inputs.
- Explain what changes in ion channels in the axonal membrane are responsible for different components of the action potential.
- Explain how action potential conduction velocity is related to myelination and axon diameter, and why conduction of action potentials is unidirectional.

1. Why does the Goldman equation produce a more accurate calculation of membrane resting potential than the Nernst equation?
2. How do graded membrane potentials enable the activity in the axon of a neuron to integrate the various dendritic inputs to that neuron?

3. Why is an action potential self-regenerating?
4. A clinical nerve conduction velocity test electrically stimulates a nerve at one location and records the muscle response at a more distal location. Why is this test used when a physician suspects a demyelinating disease?

Having described how APs are generated and transmitted along axons, we will next address the question of what happens when an AP reaches the axon terminal. How is its signal communicated to the next cell—which could be another neuron, a muscle cell, or a secretory cell?

***connect the concepts** The passive and active mechanisms that transport materials across cell membranes are discussed in [Key Concepts 6.3](#) and [6.4](#). The passive mechanisms are membrane proteins that form channels (see [Figure 6.10](#)), and the active mechanisms (which require ATP) are membrane proteins engaged in active transport (see [Figure 6.14](#)).

44.3 Neurons Communicate with Other Cells

Neurons communicate with each other and with other cells at synapses. In **electrical synapses**, which are common among invertebrates, the AP spreads directly from presynaptic to postsynaptic cell. The most common type of synapse in the vertebrate nervous system is the **chemical synapse**, in which neurotransmitters released from a presynaptic cell induce changes in a membrane potential of a postsynaptic cell. This section begins with a discussion of the synapses between neurons and muscle cells. We then consider the diversity in synapses between neurons and how they integrate information.

electrical synapse A type of synapse at which action potentials spread directly from presynaptic cell to postsynaptic cell. (Contrast with chemical synapse.)

chemical synapse Neural junction at which neurotransmitter molecules released from a presynaptic cell induce changes in a postsynaptic cell. (Contrast with electrical synapse.)

focus your learning

Action potentials arriving at a chemical synapse such as the neuromuscular junction trigger an influx of Ca^{2+} that activates the molecular machinery responsible for vesicular release of neurotransmitter.

Gap junctions are comprised of connexins connecting electrically-coupled neurons through a pore, enabling ions and small molecules to cross from one cell to another.

The action of a neurotransmitter depends on the nature of the postsynaptic receptor.

Neurotransmitter action can be terminated by diffusion, reuptake, or degradation.

Agonists and antagonists are drugs that target specific receptors.

The neuromuscular junction is a model chemical synapse

Neuromuscular junctions are synapses between neurons and skeletal muscle cells. They are excellent models for how chemical synaptic transmission works. Neurons that control muscles are called motor neurons. Like other neurons, a motor neuron has only one axon, but that axon can branch into numerous axon terminals that form many synapses with muscle cells. At each axon terminal an enlarged knob or buttonlike structure contains membrane-bound vesicles filled with neurotransmitter molecules. The neurotransmitter used by all vertebrate neuromuscular synapses is **acetylcholine (ACh)**. ACh is released by exocytosis when the membrane of a vesicle containing this neurotransmitter fuses with the presynaptic membrane of the axon terminal.

neuromuscular junction Synapse (point of contact) where a motor neuron axon stimulates a muscle fiber cell.

acetylcholine (ACh) A neurotransmitter that carries information across vertebrate neuromuscular junctions and some other synapses. It is then broken down by the enzyme acetylcholinesterase (AChE).

The postsynaptic membrane of the neuromuscular junction is a modified part of the muscle cell membrane called a **motor end plate**. It appears as a depression in the muscle cell membrane, and the terminals of the motor neuron sit in the depression. The space between the presynaptic membrane and the postsynaptic membrane is the **synaptic cleft**, which in chemical synapses is about 20-40 nanometers wide. ACh released into the cleft by the presynaptic cell diffuses across to the postsynaptic membrane (**Focus: Key Figure 44.11**).

motor end plate The depression in the postsynaptic membrane of the neuromuscular junction where the terminals of the motor neuron sit.

synaptic cleft The space between the presynaptic cell and the postsynaptic cell in a chemical synapse.

focus: key figure

Figure 44.11 Chemical Synaptic Transmission Begins with the Arrival of an Action Potential The neuromuscular junction is a typical chemical synapse. Events shown here are similar for other neurotransmitters at other synapses. Both chemically gated and voltage gated ACh receptors are found in the motor end plate. These are non-selective cation channels, but are more permeable to Na^+ than to K^+ (inset). When one of the chemically gated receptors binds ACh, its channel pore opens and the net increase in Na^+ permeability of the postsynaptic membrane depolarizes it. The depolarization spreads beyond the motor endplate activating voltage gated Na^+ channels in the muscle cell membrane, depolarizing it and initiating an action

potential. The enzyme acetylcholinesterase (AChE) breaks down ACh in the synapse, closing the chemically gated channels. The breakdown products (acetate and choline) are taken up by the presynaptic membrane and resynthesized into more ACh.

Q: If this synapse were between neurons, and the neurotransmitter were inhibitory rather than excitatory, what chemically gated channels would you expect to be on the postsynaptic membrane?

Media Clip 44.1 Put Some ACh Into It! www.Life11e.com/mc44.1

Animation 44.3 **Synaptic Transmission** www.Life11e.com/a44.3

The arrival of an action potential causes the release of neurotransmitter

Neurotransmitter is released when an AP arrives at the axon terminal and causes the opening of voltage-gated Ca^{2+} channels in the presynaptic membrane. Because the Ca^{2+} concentration is greater outside the cell than inside, Ca^{2+} enters the axon terminal. This increase in Ca^{2+} inside the axon terminal causes the vesicles containing neurotransmitter to fuse with the presynaptic membrane and empty their contents into the synaptic cleft.

In neuromuscular synapses, vesicle fusion and emptying is all-or-none. The vesicle membrane is incorporated into the presynaptic membrane, which actually gets larger as a result—at least until the extra membrane is recycled through endocytosis. The membrane is reprocessed by the cell into new vesicles that are refilled with neurotransmitter.

Synaptic functions involve many proteins

Our description of the release of neurotransmitter from the presynaptic membrane may seem simple, but it involves hundreds of proteins that are responsible for various aspects of the process: vesicle formation, transport of neurotransmitter into vesicles, anchoring of vesicles to cytoskeletal elements, docking of the vesicles with the presynaptic membrane, fusion of the vesicular and cell membranes, and endocytosis of the vesicle membrane for recycling.

Some of these proteins are the targets of toxins. For example, botulinum and tetanus toxins from bacteria of the genus *Clostridium* act on several of the proteins necessary for the docking of vesicles to the presynaptic membrane, resulting in diseases that are frequently fatal. Botulinum toxin impairs muscle contraction, whereas tetanus toxin causes uncontrolled muscle contraction. Poisons can become medicines. Botulinum toxin (in the form of Botox) is used therapeutically to subdue muscle spasms and cosmetically to reduce wrinkles.

The postsynaptic membrane responds to neurotransmitter

When acetylcholine is released at a synapse, some of it diffuses across the synaptic cleft and binds to ACh receptors on the postsynaptic membrane. The postsynaptic membrane of the motor end plate is highly folded. ACh receptors are on the crests of the folds, and voltage-gated cation channels are at the bottoms of the folds and in the surrounding muscle cell membrane (see [Figure 44.11](#)). The ACh receptors are gated channels that allow both Na^+ and K^+ to flow through, but since the electrochemical gradients favor a net influx of Na^+ , the response of the motor end plate to ACh is to depolarize. That graded potential reflects the number of receptors activated. If sufficient numbers of receptors are activated, the membrane depolarization spreads to the depths of the folds of the motor end plate membrane and to the surrounding muscle cell membrane, which contain voltage-gated Na^+ channels.

The spreading depolarization of the motor end plate activates the voltage-gated Na^+ channels

and causes the firing of an AP. This AP is then conducted throughout the muscle cell's system of membranes, causing the cell to contract. We will discuss the contraction of muscle cells in greater detail in Key Concept 47.10.

How much neurotransmitter is enough? Neither a single ACh molecule nor the contents of an entire vesicle (about 10,000 ACh molecules) will bring the membrane of a muscle cell to threshold. However, a single AP in an axon terminal releases the contents of about 100 vesicles—more than enough to fire an AP in the muscle cell and cause it to contract.

Activity 44.1 **Neurons and Synapses Simulation** www.Life11e.com/ac44.1

Synapses can be excitatory or inhibitory

The synapses between vertebrate motor neurons and muscle cells are always excitatory. The motor end plates always respond to ACh with a graded potential that is less negative than the resting potential (depolarization). However, synapses between neurons are frequently inhibitory; such a synapse causes hyperpolarization of the postsynaptic membrane or simply makes it less likely that membrane potential will reach threshold for the voltage gated Na⁺ channels. For example, there are more Cl⁻ ions outside than inside the cell. However, in a mammalian neuron the equilibrium potential for Cl⁻ is around -60mV. Given a resting potential that is also around -60 mV, opening of Cl⁻ channels will not hyperpolarize the membrane, but if these channels are open, it will make it more difficult to raise the membrane potential to the threshold for the voltage gated Na⁺ channels.

Recall that most neurons have many dendrites. Axon terminals from many other neurons can form synapses with those dendrites and with the cell body. The axon terminals of different presynaptic neurons can store and release different neurotransmitters, and the cell membrane of the dendrites and cell body of a postsynaptic neuron can have receptors for a variety of neurotransmitters. The mix of synaptic activity impinging on a neuron will cause it to have a graded membrane potential that can be either more positive or more negative than its resting potential.

The postsynaptic neuron sums excitatory and inhibitory input

What determines when an individual neuron will fire an AP? As you just learned, the sum of excitatory and inhibitory postsynaptic potentials creates a graded membrane potential in the postsynaptic cell body. This summation ability is the major mechanism by which the nervous system integrates information. A neuron may receive 1,000 or more synaptic inputs, but it has only one output: APs in a single axon. At any one time, the information from all of the active inputs is translated into the rate at which that neuron generates APs in its axon.

For most neurons, summation takes place in the axon hillock at the base of the axon. The cell membrane of the axon hillock is not insulated by glia and has many voltage-gated Na⁺ channels. Excitatory and inhibitory postsynaptic potentials from synapses anywhere on the dendrites or the cell body spread to the axon hillock by local current flow. If the resulting graded potential depolarizes the axon hillock to threshold, it fires an AP. Because postsynaptic potentials decrease in strength as they spread from the site of the synapse, a synapse at the tip of a dendrite has less influence than a synapse on the cell body, near the axon hillock.

Excitatory and inhibitory postsynaptic potentials are summed over space and over time. **Spatial summation** adds up the simultaneous influences of synapses at different sites on the postsynaptic cell (**Figure 44.12A**). **Temporal summation** adds up postsynaptic potentials generated at the same site in a rapid sequence (**Figure 44.12B**).

spatial summation In the production or inhibition of action potentials in a postsynaptic cell, the interaction of depolarizations and hyperpolarizations produced at different sites on the

postsynaptic cell. (Contrast with temporal summation.)

temporal summation In the production or inhibition of action potentials in a postsynaptic cell, the interaction of depolarizations or hyperpolarizations produced by rapidly repeated stimulation of a single point on the postsynaptic cell. (Contrast with spatial summation.)

Figure 44.12 The Postsynaptic Neuron Sums Information Individual neurons sum excitatory and inhibitory postsynaptic potentials over space (A) and time (B). When the sum of the potentials depolarizes the axon hillock to threshold, the neuron generates an action potential.

Electrical synapses are fast but do not integrate information well

Electrical synapses are different from chemical synapses because they couple neurons electrically. Electrical synapses contain numerous ***gap junctions**. At these synapses, the presynaptic and postsynaptic cell membranes are separated by a space of only 2-3 nanometers, and membrane proteins called connexins link the two neurons by forming pores that connect the cytoplasm of the two cells (see [Figure 7.16A](#)). Electrical current as well as ions and small molecules can pass directly from cell to cell through these pores. As a result, transmission at electrical synapses is very fast and can proceed in either direction. In comparison, transmission at chemical synapses is slow and unidirectional.

The properties of electrical synapses make them especially well adapted for processes that have to be fast—for example, escape from danger. They are also effective means of achieving synchronous activity of populations of cells. Electrical synapses are less common in the nervous

systems of vertebrates than are chemical synapses. The major reason is that they offer fewer means for integration of information. Electrical synapses are almost exclusively excitatory whereas chemical synapses are both excitatory and inhibitory. Electrical synapses are not well suited for temporal summation of inputs. Also, because of their relative simplicity of structure and function, electrical synapses offer fewer possible mechanisms for plasticity which is the foundation of learning and memory. One advantage they do have is the ability to synchronize large numbers of cells.

The action of a neurotransmitter depends on the receptor to which it binds

More than 100 neurotransmitters are now recognized, and more will surely be discovered. Acetylcholine (ACh) is an important neurotransmitter because it is the substance the nervous system uses in signaling muscles to contract. ACh also plays roles in certain synapses between neurons in the brain, but it accounts for only a small percent of the total neurotransmitter content of the brain.

The workhorse neurotransmitters of the brain are three simple amino acids: glutamate, which is usually excitatory, and glycine and γ -aminobutyric acid (GABA), which are usually inhibitory. The integration of information at the cellular level is a balance between excitation and inhibition, so it is understandable that excessive inhibition such as you saw in the Down syndrome mice described at the start of this chapter could impair an animal's ability to process and integrate new information. Indeed, when GABA's inhibitory action in these mice was reduced by a drug that blocks the GABA receptor, the learning ability of the mice improved, as described in

Investigating Life: Can Learning Be Restored in Mouse Models of Down Syndrome?

Can Learning Be Restored in Mouse Models of Down Syndrome?

experiment

Original Paper: Colas, D., B. Chuluun, D. Warrier, M. Blank, D. Z. Wetmore, P. Buckmaster, C. C. Garner and H. C. Heller. 2013. Short-term treatment with the GABA antagonist pentylenetetrazole produces a sustained procognitive benefit in a mouse model of Down's syndrome. *British Journal of Pharmacology* 169: 963–973.

If the learning disability in the mouse model of Down syndrome (DS) is due to overinhibition, then reducing the activity of the major inhibitory neurotransmitter, GABA, might improve learning in these mice.

HYPOTHESIS▶ The inability of DS model mice to learn and remember experiences as well as wild-type (WT) mice is due to overactive GABA signaling in their brains. If GABA signaling is reduced, the ability of mice to perform learning tasks should improve.

METHOD

1. Keep DS and WT mice of the same age on a 12-hour:12-hour light–dark cycle. At the same time each morning, for 2 weeks, inject the mice in the experimental group with the drug pentylenetetrazole (PTZ), which blocks the action of GABA. Use three different doses. Inject the control mice with saline. The doses are measured as mg PTZ/kg body weight of mouse.
2. Following completion of the two-week drug-dosing protocol, evaluate the mice using the Novel Object Recognition (NOR) test. For training, place each mouse in a 4-square-foot arena that contains two objects such as chessmen or small bottles. Allow the mouse to explore the objects for 10 min and then return it to its home cage. An acceptable baseline is when the mouse spends the same amount of time exploring each object. Test again 1 day later, placing the mouse back in the arena but with one of the objects changed (the novel object). If the mouse spends more time exploring the novel object, that is evidence that it remembered the original object from the day before.

3. Quantify the mouse's behavior as a NOR preference (time spent exploring object A/time spent exploring objects A and B $\times$ 100%). For the testing trial, A is the novel object. A NOR preference of 50% means the mouse spent equal amounts of time with each object, and therefore did not remember the objects it explored previously. A NOR preference significantly greater than 50% means the mouse spent more time exploring the novel object and is evidence that the mouse remembered the objects it saw before.

RESULTS

Data are NOR preference percentages $\pm$ 1 SEM (standard error of the mean). An asterisk (*) indicates $P < 0.01$ for difference between training (blue) and testing (orange) results as determined by a t -test: **, $P < 0.001$.

CONCLUSION

The saline treatments (controls) show that the WT mice can recognize the novel object 24 hr after training and that the DS mice cannot. PTZ treatment had no effect on the WT mice. PTZ treatment at 0.3 and 0.03 mg/kg improved the ability of the DS mice to remember the familiar objects and therefore recognize the novel object, whereas treatment at 0.01 mg/kg did not.

investigatinglife work with the data follows on next page.

work with the data

All of the PTZ injections in the experiment described above were given to the mice early in the light phase of their day. This is the time when these nocturnal animals are normally sleeping. The researchers therefore asked whether the same results could be obtained if the treatments were delivered during the dark phase of the day, when the mice are usually active and exploring. They obtained the following data:

Group	Treatment	
	Saline	PTZ 0.3 mg/kg
WT Mice Training	55.0 $\pm$ 3.1	55.4 $\pm$ 2.4
DS Mice Training	51.9 $\pm$ 2.4	50.7 $\pm$ 2.0
WT Mice Testing	65.8 $\pm$ 5.3*	67.4 $\pm$ 4.9*
DS Mice Testing	53.7 $\pm$ 4.7	51.3 $\pm$ 6.9

QUESTIONS

1. How does the learning ability of the WT and DS mice compare during the dark phase of the day, and does this result differ from when the training and testing are done during the light phase?
2. Describe any difference between the effect of the PTZ treatment on the performance of the WT and DS mice on the NOR task during the light and dark phases of the day.

A similar **work with the data** exercise may be assigned in **LaunchPad**.

Another important group of neurotransmitters in the brain is the monoamines, which are derivatives of amino acids. They include dopamine and norepinephrine (derivatives of tyrosine) and serotonin (a derivative of tryptophan). Peptides also function as neurotransmitters; for example, endorphins and enkephalins are the body's opiates and modulate the sensation of pain. Another peptide, substance P, transmits pain sensations. Even a gas, nitric oxide, is used by neurons as an intercellular messenger (see [Figure 7.13](#)).

Neurotransmission is complex in part because each neurotransmitter has multiple receptor types. ACh, for example, has two receptor types: nicotinic receptors and muscarinic receptors. All of the ACh receptors in skeletal muscle are nicotinic. Both types of ACh receptors are found in the brain and spinal cord, where nicotinic receptors tend to be excitatory and muscarinic receptors tend to be inhibitory. ACh actions can differ outside the brain and spinal cord as well. ACh acting through nicotinic receptors causes the smooth muscle of the gut to increase its motility, but ACh acting through muscarinic receptors causes cardiac muscle to hyperpolarize

and therefore to slow down. There are many more examples of neurotransmitters that have different effects in different tissues, but the important thing to remember is that the action of a neurotransmitter depends on the receptor to which it binds. In addition, turning neurotransmitter action off is as important as turning it on.

 Activity 44.2 Neurotransmitters www.Life11e.com/ac44.2

To turn off responses, synapses must be cleared of neurotransmitter

If released neurotransmitter molecules simply remained in the synaptic cleft, the postsynaptic membrane would become saturated and receptors would be constantly activated. The postsynaptic cell would remain hyperpolarized or depolarized and would be unresponsive to additional APs arriving at the presynaptic cell. The more rapidly neurons can respond to input, the more information they can process in a given amount of time. Thus neurotransmitter must be cleared from the synaptic cleft shortly after it is released by the axon terminal.

Neurotransmitter action can be terminated in several ways. First, enzymes can destroy the neurotransmitter. Acetylcholine, for example, is rapidly destroyed by the enzyme acetylcholinesterase (AChE), which is present in the synaptic cleft in close association with ACh receptors on the postsynaptic membrane (see [Figure 44.12](#)). When AChE is inhibited, ACh lingers in the synaptic cleft, causing spastic (contracted) muscle paralysis and usually resulting in death. Some of the most deadly nerve gases developed for chemical warfare work by inhibiting AChE. Some agricultural insecticides, such as malathion, also inhibit AChE and can poison farm workers if used without safety precautions.

Neurotransmitter can also simply diffuse away from the cleft or be taken back up by the presynaptic membrane to be recycled. Glial cells also take up neurotransmitters. An antidepressant drug commonly prescribed under the brand name Prozac slows the reuptake of the neurotransmitter serotonin, thus enhancing serotonin's activity at the synapse.

The diversity of receptors makes drug specificity possible

Many drugs used to treat the nervous system act by modulating specific synaptic interactions. Drugs that mimic or potentiate the effect of a neurotransmitter are called [agonists](#); those that block the actions of neurotransmitters are called [antagonists](#). For example, morphine is an agonist at the endorphin receptor and therefore blocks pain. Propranolol, a widely used beta blocker, is an antagonist of receptors in the fight-or-flight response and therefore decreases panic attacks and anxiety. A major emphasis in neurobiology is to identify neurotransmitter receptor subtypes and design drugs that selectively bind to them to have highly specific effects on nervous system activity.

agonist A chemical substance (e.g., a neurotransmitter) that elicits a specific response in a cell or tissue. (Contrast with antagonist.)

antagonist A biochemical substance (e.g., a drug) that blocks the normal action of another biochemical substance. (Contrast with agonist.)

44.3 recap

Chemical synapses involve the release of neurotransmitter molecules stored in vesicles in the presynaptic terminal. APs reaching that terminal cause the fusion of vesicles with the presynaptic membrane, releasing neurotransmitter that can then bind to receptors on the postsynaptic membrane and influence its membrane potential. At excitatory synapses, the neurotransmitter causes depolarization of the postsynaptic membrane, and at inhibitory

synapses the neurotransmitter hyperpolarizes or stabilizes the postsynaptic membrane potential. There is a great diversity of neurotransmitters and their receptors. At electrical synapses the AP moves directly between pre- and postsynaptic cells.

learning outcomes

You should be able to:

- Describe the events at a neuromuscular synapse, beginning with the action potential in the presynaptic neuron and ending with the response of the postsynaptic cell.
 - Compare the characteristics of electrical versus chemical synapses.
 - Discuss how the properties of transmission differ for electrical and chemical synapses, and why chemical synapses present a greater variety of postsynaptic responses than do electrical synapses.
 - Discuss how the properties of chemical synapses present a variety of postsynaptic responses.
 - Describe the reasons why synaptic transmission is typically transitory.
-

1. What are the two types of cation channels in the motor end plate, and what are their functions?
 2. How can the same neurotransmitter be excitatory to some postsynaptic neurons and inhibitory to others?
 3. Sarin is a colorless, odorless liquid that is highly lethal. It irreversibly inhibits the enzyme acetylcholinesterase. Explain why victims of sarin poisoning generally die of asphyxiation.
 4. Explain why parts of nervous systems that integrate complex information use chemical rather than electrical synapses.
-

Now that you understand how neurons communicate with each other, we will explore how they are organized into circuits and systems that process sensory information and generate responses to that information.

***connect the concepts** The proteins that form gap junctions between cells, including neurons, are discussed in [Key Concept 6.2](#).

44.4 Neurons and Glia Form Information-Processing Circuits

Nervous systems can process information because their neurons are organized into [neural networks](#). These networks include three functional categories of neurons that are responsible for input, output, and integration:

neural network An organized group of neurons that contains three functional categories of neurons—afferent neurons, interneurons, and efferent neurons—and is capable of processing information.

- [Afferent neurons](#) carry sensory information into the nervous system. That information comes from specialized sensory cells that transduce (convert) various kinds of sensory stimuli (e.g., light, heat, pressure) into APs.

afferent (af' ur unt) [L. *ad*: toward + *ferre*: to carry] Carrying to, as in neurons that carry impulses to the central nervous system (**afferent neurons**), or a blood vessel that carries blood to a structure (**afferent arterioles**). (Contrast with efferent.)

- **Efferent neurons** carry commands to physiological and behavioral effectors such as muscles and glands.
- [Interneurons](#) integrate and store information and communicate between afferent and efferent neurons.

interneuron A neuron that communicates information between two other neurons.

focus your learning

From invertebrates to vertebrates, nervous systems have evolved with increasing complexity from simple nerve nets to clusters of neurons (ganglia) to the development of anterior brain structures.

The knee-jerk reflex involves a simple circuit with input from sensory neurons stimulating interneurons and motor neurons in the spinal cord that trigger the quadriceps to contract.

Nervous systems range in complexity

Simple animals such as cnidarians (sea anemones, for example) process information with a limited number of simple neural networks that do little more than provide direct lines of communication from sensory cells to effectors; there is little or no integration or processing of signals (**Figure 44.13A**). The cnidarian's [nerve net](#) is most developed around the tentacles and the oral opening, where it facilitates detection of food or danger and causes tentacles to extend or retract.

Figure 44.13 Nervous Systems Vary in Size and Complexity In animal species with increasingly complex sensory and behavioral abilities, information processing is increasingly centralized in ganglia (collections of neurons) or in a brain.

nerve nets Diffuse, loosely connected aggregations of nervous tissues in certain non-bilaterialian animals such as cnidarians.

Animals that are more complex and move about in search of food and mates must process and integrate larger amounts of information. Even earthworms fit this description, and their increased need for information processing is met by higher numbers of neurons organized into clusters of neuronal cell bodies called **ganglia** (singular *ganglion*). Ganglia serving different functions may be distributed around the body, as in earthworms (**Figure 44.13B**). In animals that are bilaterally symmetrical, ganglia frequently come in pairs, one on each side of the body (**Figure 44.13C**). Also, as animals increase in complexity, some ganglia may become enlarged or fused together at the anterior end, forming a **brain**. Small nervous systems of invertebrates can be remarkably complex. Consider the nervous systems of spiders that have programmed within them the thousands of precise movements necessary to construct an intricate web without prior experience or opportunities to learn the specific web architecture of their species.

brain The centralized integrative center of a nervous system.

In vertebrates, most cells of the nervous system are found in the central nervous system (CNS). The CNS includes the brain and the spinal cord, which are the sites of most information processing, storage, and retrieval (**Figure 44.13D**). Information is transmitted from sensory cells to the CNS and from the CNS to cells that respond (effectors) via neurons that extend or reside outside the brain and the spinal cord. These sensory and effector neurons and their supporting cells are the peripheral nervous system.

Reflexes are controlled by simple circuits involving sensory neurons, interneurons, and effectors

A reflex is a behavioral or physiological response that does not require conscious information

processing—it is autonomic, meaning an involuntary or unconscious reaction. Examples are salivating at the sight or smell of food, and the jerk of your lower leg when a physician taps your knee with a small rubber hammer. The knee-jerk reflex involves a very simple neural circuit involving just a few neurons that connect with each other in the spinal cord. Thus it is called a [spinal reflex](#). A cross section of the human spinal cord reveals a central area of gray matter in the shape of a butterfly, surrounded by areas of white matter (see [Figure 44.14](#)). In the nervous system, [gray matter](#) is rich in neuronal cell bodies, and [white matter](#) contains myelinated axons. The gray matter of the spinal cord contains the cell bodies of the spinal neurons; the white matter contains myelinated axons that conduct information up and down the spinal cord.

spinal reflex The conversion of afferent to efferent information in the spinal cord without participation of the brain.

gray matter In the nervous system, tissue that is rich in neuronal cell bodies. (Contrast with white matter.)

white matter In the central nervous system, tissue that is rich in axons. (Contrast with gray matter.)

Spinal nerves extend from the spinal cord at regular intervals on each side. Each spinal nerve has two roots, one connecting with the dorsal horn of the gray matter, the other with the ventral horn. The afferent (sensory) axons in a spinal nerve enter the spinal cord through the dorsal root, and the efferent (motor) axons leave through the ventral root. The neural circuit of the knee-jerk reflex is diagrammed in [Figure 44.14](#). The tap of the physician's rubber hammer stretches the tendon going over the knee. That tendon attaches the muscle of the upper leg to bone in the lower leg. Stretching the tendon stretches muscle fibers in the upper leg, and stretch receptors in that muscle transduce the physical stimulus into APs. The APs are then conducted by a sensory neuron into the dorsal horn of the spinal cord. That sensory neuron goes all the way to the ventral horn and synapses onto a motor neuron, which fires APs. The axon of that motor neuron travels out through the ventral horn of the spinal cord and extends all the way to the same muscle that initially was stretched, causing that muscle to contract.

Figure 44.14 A Neural Network in the Spinal Cord Generates the Knee-Jerk Reflex Sensory (afferent) information enters the spinal cord through the dorsal horns, and motor (efferent) output leaves it via the ventral horns. Information travels to the brain in white matter tracts. Interneurons make connections within the spinal cord that result in a complex, coordinated behavior pattern.

Animation 44.4 **Information Processing in the Spinal Cord** www.Life11e.com/a44.4

What is the function of the spinal knee-jerk reflex? This simple circuit senses increased load on a muscle and adjusts its level of contraction to match the load. Most spinal reflexes are more complex. For example, limb movement is controlled by antagonistic sets of muscles that work against each other. When one member of an antagonistic set of muscles contracts, it bends (flexes) the limb; it is therefore called a flexor. The antagonist muscle, the extensor, straightens (extends) the limb. For a limb to move, one muscle of the pair must relax while the other contracts. Thus sensory input that activates the motor neuron of one muscle also inhibits its antagonist. This coordination is achieved by an interneuron between the sensory neuron and the motor neuron of the antagonist muscle (see [Figure 44.15](#)). Thus the reciprocal inhibition of antagonistic muscles involves at least two synapses.

The withdrawal reflex is an example of a polysynaptic spinal reflex that involves many interneurons. When you step on a tack, you immediately pull back your foot, but you don't fall over because many other muscles change your posture. The tack stimulates pain receptors in the foot, and the sensory neurons transmit APs into the dorsal horn of the spinal cord on the same side of the body. In the dorsal horn, these neurons synapse with a variety of interneurons. Some send the pain information through their axons to the brain, resulting in the conscious sensation of pain. But even before the brain is aware of the pain, other interneurons coordinate the withdrawal of the foot with actions of other muscles to shift your weight onto the other leg. Thus a rather complex suite of movements is coordinated by a network of interneurons in the spinal cord. By extension, you can appreciate how much more complex the neural networks are that enable you to execute complex movements in time with music and coordinated with another

person—in other words, to dance.

The vertebrate brain is the seat of behavioral complexity

Vertebrates differ greatly in their behavioral complexity and in their physiological specializations, and their neural networks reflect this diversity. **Figure 44.15** shows the brains of four vertebrate species of similar body mass drawn to the same scale.

Figure 44.15 Brains Vary in Size and Complexity The brains of four vertebrate species—all of which may have a similar body mass — show immense differences. Note that the brainstem, which is involved in physiological regulation and stereotypic behavior, differs less among these species than does the cerebrum, which is responsible for complex behavior and learning.

Q: What sensory capability do you think is well developed in the pig?

The human nervous system contains an estimated 10^{11} neurons. A given neuron in the brain can have 1,000 or more synapses. Thus the human brain can contain 10^{14} synapses (10^{11} neurons $\times$ 10^3 synapses per neuron). Then there are the glia. A single astrocyte might participate in 100,000 synapses while at the same time monitoring signals in the extracellular fluid and the blood. In addition, synapses are not constant but can be highly plastic. They can

increase or decrease in number and size, and they can become more or less sensitive.

This astronomical number of neurons and synapses is divided into thousands of distinct but interacting networks that function in parallel. The possible number of informational networks in the brain is almost infinite, and therein lies the incredible ability of the human brain to process information, to learn, to do complex tasks, to remember, and to have emotions.

44.4 recap

Nervous systems are composed of neural networks that include afferent neurons, interneurons, and efferent neurons. Nervous systems range in complexity from simple nerve nets to the human brain. The spinal knee-jerk reflex is an example of a simple neural network, but networks that control more complex behavior are much more complicated.

learning outcomes

You should be able to:

- Distinguish the central from the peripheral nervous system and recognize how these systems range in complexity among different species.
- Analyze a simple circuit and map the communication between afferent and efferent neurons.

1. What are ganglia, and why are they concentrated in the anterior region of many invertebrates?
2. Draw or describe the flow of information from stimulus to response in the knee-jerk reflex circuit.
3. In the knee-jerk reflex circuit, how can the same stimulus cause contraction in one muscle and relaxation in another?
4. When considering fish, then reptiles, then mammals, which part of the vertebrate brain increases most in size?

▶▶ investigatinglife

QA Can learning be restored in mouse models of Down syndrome?

Some neurotransmitter-receptor combinations excite activity in the postsynaptic neuron, depolarizing it and making it likely to fire an AP. Other neurotransmitter-receptor combinations inhibit the responses of the postsynaptic cell. Neurons integrate information by summing excitatory and inhibitory synaptic inputs. Over-inhibition in the nervous system can arise when too much inhibitory neurotransmitter (such as GABA) is released, or if postsynaptic cells have too many receptors for inhibitory neurotransmitters. Drugs that decrease the synthesis and release of the inhibitory neurotransmitter can reduce the inhibition, as can drugs that block the receptors for such neurotransmitters. In the case of the Down syndrome model mice, drugs such as pentylentetrazole, which blocked the GABA receptors (which function also as Cl^- channels), reduced the level of inhibition in the mouse nervous system and increased the ability of the mice to learn and form memories.

Future directions

Going from experiments on the effects of drugs on mice to a therapy for humans is a difficult path. To protect patients, the Federal Food and Drug Administration (FDA) has a rigorous procedure for approving drugs for human use. After a candidate drug is shown to be effective and safe in animal models, four stages of approval must be passed before a drug is allowed on the market. In Phase 0, the first in-human trials are conducted on a small group of volunteers to study how the body absorbs, distributes, metabolizes, and excretes the drug, and whether it has any obvious side effects. In Phase 1, trials are conducted in a small group of volunteers to evaluate safety and dosage, and again to look for side effects. Phase 2 involves a larger group of subjects who have the disease that the drug is expected to treat, to see if it is effective and safe. The comparison is with a placebo. In Phase 3, trials are conducted with a large group of patients to assess the drug's effectiveness and safety, and to compare it with other commonly used treatments. Each of these phases must be reviewed by the FDA and approved before proceeding to the next phase. Pentyl-enetetrazole is currently in Phase 2 trials.

► 44.1 Neurons and Glia Are Unique Cells of Nervous Systems

- The cells of the nervous systems include many types of **neurons and glia**.
- All neurons can generate and conduct ionic electrical signals, and most can generate **action potentials (APs)**. Glia support and modulate the activities of neurons but do not generate APs .

action potentials (APs) Generated by neurons, these are electrical signals that transmit information via waves of depolarization or hyperpolarization of the cell membrane.

- A neuron generally receives information via its dendrites, of which there can be many, and transmits information via its single axon, which ends in **axon terminals**. **Review Figures 44.1, 44.2**

axon terminal The end portion of an axon, which passes action potentials to another cell. Axon terminals can form synapses and release neurotransmitter.

- Where neurons and their target cells meet, information is transmitted across specialized junctions called **synapses**.

synapse (sin' aps) [Gk. *syn*: together + *haptein*: to fasten] A specialized type of junction where a neuron meets its target cell (which can be another neuron or some other type of cell) and information in the form of neurotransmitter molecules is exchanged across a synaptic cleft.

- Glia include **Schwann cells** and **oligodendrocytes**, both of which generate **myelin** sheaths on axons. **Review Figure 44.3**

Schwann cell A type of glial cell that myelinates axons in the peripheral nervous system.

oligodendrocyte A type of glial cell that myelinates axons in the central nervous system.

myelin (my' a lin) Concentric layers of plasma membrane that form a sheath around some axons; myelin provides the axon with electrical insulation and increases the rate of transmission of action potentials.

- Glia also include **astrocytes**, which support neurons metabolically, modulate synaptic signaling, and contribute to the **blood-brain barrier**.

astrocyte [Gk. *astron*: star] A type of glial cell that contributes to the blood–brain barrier by surrounding the smallest, most permeable blood vessels in the brain.

► 44.2 Neurons Generate and Transmit Electric Signals

- Neurons have an electric charge difference across their cell membranes. This **membrane potential** is generated by ion gradients (due to ion transporters) and ion channels. When a neuron is not stimulated, its membrane potential is referred to as the **resting potential**. [Review Figure 44.4](#), [Animation 44.1](#)

membrane potential The difference in electrical charge between the inside and the outside of a cell, caused by a difference in the distribution of ions.

resting potential The membrane potential of a living cell at rest. In cells at rest, the interior is negative to the exterior. (Contrast with action potential.)

- The **sodium-potassium pump** concentrates K^+ on the inside of a neuron and Na^+ on the outside. Leak K^+ channels in the cell membrane allow K^+ to diffuse out leaving behind unbalanced negative charges, creating the resting potential. [Review Figure 44.5](#)
- **Patch clamping** allows the study of single ion channels. [Review Figure 44.6](#)

patch clamping Technique for isolating a tiny patch of membrane to allow the study of ion movement through a particular channel.

- The resting potential is perturbed when ion channels open or close, changing the permeability of the cell membrane to charged ions. Through this mechanism, the cell membrane can become **depolarized** or **hyperpolarized** and therefore have a **graded membrane potential** response to input. [Review Figure 44.7](#)

graded membrane potential Small local change in membrane potential caused by opening or closing of ion channels.

- An AP is a rapid transient reversal in charge across a portion of the cell membrane resulting from the sequential opening and closing of voltage-gated Na^+ and K^+ channels. These changes in voltage-gated channels occur when the cell membrane depolarizes to a **threshold** level. [Review Figure 44.8](#), [Animation 44.2](#)

threshold The level of depolarization that causes an electrically excitable membrane to fire an action potential.

- APs are all-or-none, self-regenerating events. They are conducted down axons because local current flow depolarizes adjacent regions of membrane and brings them to threshold. [Review Figure 44.9](#)
- In myelinated axons, APs appear to jump between **nodes of Ranvier**, areas of axonal cell membrane that are not covered by myelin. [Review Figure 44.10](#)

node of Ranvier A gap in the myelin sheath covering an axon; the point where the axonal membrane can fire action potentials.

► 44.3 Neurons Communicate with Other Cells

- Neurons communicate with each other and with other cell types by transmitting information over **electrical synapses** or by the transmission of molecular signals called

[neurotransmitters](#) over [chemical synapses](#).

electrical synapse A type of synapse at which action potentials spread directly from presynaptic cell to postsynaptic cell. (Contrast with chemical synapse.)

neurotransmitter A substance produced in and released by a neuron (the presynaptic cell) that diffuses across a synapse and excites or inhibits another cell (the postsynaptic cell).

chemical synapse Neural junction at which neurotransmitter molecules released from a presynaptic cell induce changes in a postsynaptic cell. (Contrast with electrical synapse.)

- The [neuromuscular junction](#) is a well-studied chemical synapse between a motor neuron and a skeletal muscle cell. Its neurotransmitter is [acetylcholine \(ACh\)](#), which causes depolarization of the postsynaptic membrane when it binds to its receptor at the [motor end plate](#). **Review Focus: Key Figure 44.11, Animation 44.3**

neuromuscular junction Synapse (point of contact) where a motor neuron axon stimulates a muscle fiber cell.

acetylcholine (ACh) A neurotransmitter that carries information across vertebrate neuromuscular junctions and some other synapses. It is then broken down by the enzyme acetylcholinesterase (AChE).

motor end plate The depression in the postsynaptic membrane of the neuromuscular junction where the terminals of the motor neuron sit.

- When an AP reaches an axon terminal, it causes the release of neurotransmitters, which diffuse across the [synaptic cleft](#) and bind to receptors on the postsynaptic membrane. **See Activity 44.1**

synaptic cleft The space between the presynaptic cell and the postsynaptic cell in a chemical synapse.

- Synapses between neurons can be either excitatory or inhibitory. A postsynaptic neuron integrates information by summing excitatory and inhibitory postsynaptic potentials both spatially and temporally. **Review Figure 44.12**
- There are many different neurotransmitters and even more types of receptors. The action of a neurotransmitter depends on the type of receptor to which it binds. **See Activity 44.2**
- Neurotransmitter molecules cannot be allowed to accumulate in a synapse but must be cleared to turn off responses in the postsynaptic cell. This may be done by enzymatic degradation, simple diffusion, or reuptake of the neurotransmitter.

► 44.4 Neurons and Glia Form Information-Processing Circuits

- In vertebrates, the brain and spinal cord form the [central nervous system \(CNS\)](#), which communicates with the rest of the body via the [peripheral nervous system \(PNS\)](#). The CNS increases in complexity from invertebrates to vertebrates and from fish to mammals. **Review Figures 44.14, 44.15**

central nervous system (CNS) That portion of the nervous system that is the site of most information processing, storage, and retrieval; in vertebrates, the brain and spinal cord. (Contrast with peripheral nervous system.)

peripheral nervous system (PNS) The portion of the nervous system that transmits information to and from the central nervous system, consisting of neurons that extend or reside outside the brain or spinal cord and their supporting cells. (Contrast with central nervous system.)

- **Neural networks** include **afferent neurons** and **efferent neurons**, generally connected through **interneurons**.

neural network An organized group of neurons that contains three functional categories of neurons—afferent neurons, interneurons, and efferent neurons—and is capable of processing information.

afferent (af' ur unt) [L. *ad*: toward + *ferre*: to carry] Carrying to, as in neurons that carry impulses to the central nervous system (**afferent neurons**), or a blood vessel that carries blood to a structure (**afferent arterioles**). (Contrast with efferent.)

interneuron A neuron that communicates information between two other neurons.

- A **spinal reflex** is an example of a simple neural network that integrates information and controls a response. **Review Figure 44.14**, **Animation 44.4**

spinal reflex The conversion of afferent to efferent information in the spinal cord without participation of the brain.

Go to **LearningCurve** (in **LaunchPad**) for dynamic quizzing that helps you solidify your understanding of this chapter. **LearningCurve** adapts to your responses, giving you the practice you need to master each key concept.

Original Paper: Adamantidis, A. R., F. Zhang, A. M. Aravanis, K. Deisseroth and L. de Lecea. 2007. Neural substrates of awakening probed with optogenetic control of hypocretin neurons. *Nature* 450: 420-424.

A common question in neurobiology is whether or not neurons in a particular brain region control a specific physiological or behavioral response in the animal. Recording neural activity with electrodes may show a correlation between activity of the neurons and the response, but that does not prove that those neurons *control* the response. The best evidence for whether specific neurons control a specific response is obtained by stimulating the activity of the neurons and observing — and thus proving—that the stimulation results in the response.

Dr. Karl Deisseroth's lab at Stanford University developed a means of activating specific neurons with light. They called their method "opto-genetics." Algae have light-sensitive ion channels in their membranes. The scientists isolated the gene for one of these ion channels, rhodopsin (ChR2), and developed methods to modify the gene so that when it was introduced by viral infection into a specific brain area, it would be expressed only in the neurons of interest. Using this technique, the researchers introduced ChR2 into a specific group of cells in mouse brains that produce the neurotransmitter hypocretin. They also implanted optical fibers into the brains of these mice so they could shine light on these neurons and activate them. They hypothesized that these hypocretin-releasing neurons coordinated wakefulness.

Using electrodes, the scientists recorded the action potentials of the hypocretin neurons when they were stimulated with light. [Figure A](#) shows the response of a neuron to 1 second of light, and [Figure B](#) shows the response to 15-millisecond pulses of light. Each figure superimposes two trials.

Figure A

Figure B

The researchers recorded sleep and wakefulness in the mice, and they stimulated the hypocretin neurons when the mice were asleep. The control mice received the same viral infection treatment, but the virus did not include the ChR2 gene. The time between the stimulation and the animal awakening (sleep-to-wake latency) was determined for different stimulation frequencies. They repeated the same experiment in mice that were expressing the ChR2 gene but were injected with saline or high and low doses of a drug that blocked the hypocretin receptor (HctR). [Figure C](#) shows the results of 15-ms light pulses over 10 seconds (1-30 Hz) and continuous light illumination for 10 seconds (ON). Asterisks indicate significant differences from controls.

Figure C

Questions

1. Describe the effect of 1 second of light on the membrane potential and the firing rate of the hypocretin neurons. What do these results suggest about the nature of the ChR2 protein and its response to light?
2. What is the evidence that light stimulation has a direct effect on the activity of the hypocretin neurons that are expressing ChR2?
3. Describe the effect of light stimulation on the behavior of the mice. Did the frequency of stimulation matter?
4. What is the evidence that the effects of the stimulation were due to release of hypocretin by the stimulated neurons?

45

Sensory Systems

The “holes” below the eyes of this rattlesnake are the pit organs that detect infrared radiation from the snake’s preferred prey—small rodents—with precision, even in total darkness. The forked tongue also provides information, picking up molecular signals that are detected by a specialized organ in the roof of the snake’s mouth.

key concepts

[15.2 Chemoreceptors Respond to Specific Molecules](#)

[15.3 Mechanoreceptors Respond to Physical Forces](#)

▶ investigatinglife

Seeing in the Dark

A rattlesnake can see to strike a running rodent in complete darkness. How can this be, when “seeing” means using the eyes to detect light waves, and “complete darkness” means no light? It is possible because these definitions are based on human capabilities. What we call “light” is actually only a small portion (red, orange, yellow, green, blue, indigo, and violet) of the spectrum of electromagnetic radiation. Other animals see wavelengths humans cannot. Some insects, for example, perceive patterns on flowers that reflect ultraviolet wavelengths invisible to humans (see [Figure 28.15](#)). Similarly, rattlesnakes “see” infrared wavelengths that we cannot (although at high enough levels of intensity, humans feel infrared wavelengths as heat).

It is not the snake’s eyes that perceive infrared light. Pit vipers, rattlesnakes, and their relatives have pit organs located between the nostril and the eye on each side of the skull that contain high densities of infrared-sensitive neurons. The two pits are positioned in such a way that sensory receptor cells in the pits receive directional information. Information from the pit organs goes to the same region of the brain as information from the eyes, so rattlesnakes actually do “see” the world in a range of electromagnetic radiation that is different from the human visual spectrum.

Our definition of silence is as human-oriented as our definition of darkness. “Sound” is actually pressure waves in the environment, and many animals are sensitive to pressure waves with frequencies, or pitches, we cannot hear. Elephants communicate using sound waves that are below human hearing range; such long waves travel great distances, an advantage to large animals that roam over extensive areas. Bats emit incredibly loud, brief sound pulses that are above our range of hearing. A flying bat hears echoes of these pulses bouncing off objects in the environment and can therefore avoid obstacles and catch prey in total darkness.

“Reality” is what our eyes see, our ears hear, our noses smell, and what we touch and taste. Humans sense only a limited range of the information available. Animals with different ranges of sensitivity process different sources of information and perceive the world quite differently than we do. A challenge for neurobiologists is to understand how neurons are adapted to detect different types of information in the environment.

How do pit vipers “see” in the dark?

45.1 Sensory Receptor Cells Convert Stimuli into Action Potentials

Sensory receptor cells, usually called [sensors](#) or [receptors](#), transduce (convert) physical and chemical stimuli such as light and sound waves, pressure (e.g., touch), and odorant and taste molecules into neural signals. These signals are then transmitted to the central nervous system (CNS) for processing and interpretation. The first step in this process of [sensory transduction](#) is a change in the membrane potential of the receptor cell in response to a specific type of stimulus.

sensor Cell that is responsive to a particular type of physical or chemical stimulation.

receptor See receptor protein, sensor.

sensory transduction The transformation of environmental stimuli or information into neural signals.

focus your learning

Specific stimuli cause changes in membrane potentials of sensory cells.

Sensory receptors act directly or indirectly on ion channels in the cell membrane.

Responses to sensory information depend on the neural circuits they activate.

Receptors can adapt to constant stimulation.

Sensory transduction involves changes in membrane potentials

Sensory transduction typically begins with a [receptor protein](#) that opens or closes ion channels in response to a specific stimulus such as heat, light, chemicals, mechanical force, or electric fields. The resulting change in membrane permeability to ions alters the receptor cell's membrane potential. A change in the membrane potential of a receptor cell in response to a stimulus is a [receptor potential](#). Receptor potentials are graded membrane potentials that spread over only short distances. To signal over long distances in the nervous system, receptor potentials must generate action potentials, which they can do in two ways:

receptor protein A protein that can bind to a specific molecule, or detect a specific stimulus, within the cell or in the cell's external environment.

receptor potential The change in the resting potential of a sensory cell when it is stimulated.

- . The receptor potential may trigger action potentials in the receptor cell itself.
- . The receptor potential may cause the receptor cell to release neurotransmitters that induce a postsynaptic neuron to generate action potentials.

A good model of how a receptor cell generates action potentials is the [stretch receptor](#) of a

crayfish (**Figure 45.1**). Stretching the muscle to which the stretch receptor is attached causes receptor potentials. These receptor potentials spread to the base of the cell's axon, where they generate action potentials that travel down the axon to the CNS. The rate at which action potentials are fired depends on the magnitude of the receptor potential; that magnitude, in turn, depends on how much the muscle is stretched.

stretch receptor A modified muscle cell embedded in the connective tissue of a muscle that acts as a mechanoreceptor in response to stretching of that muscle.

Figure 45.1 Stimulating a Sensory Cell Produces a Receptor Potential Signal transduction in the stretch receptor of a crayfish can be investigated by measuring the membrane potential at different places on the stretch receptor neuron while stretching the muscle innervated by that sensory neuron.

In a receptor cell that does not fire action potentials (such as the photoreceptors in the vertebrate eye), the spreading receptor potential reaches a presynaptic patch of cell membrane and induces the release of a neurotransmitter. The intensity of the stimulus influences how much neurotransmitter is released. That neurotransmitter binds to receptor proteins on an associated sensory neuron, altering its membrane potential and causing it to increase or decrease its rate of firing action potentials. In a few cases, this second cell also does not generate action potentials, but simply changes the rate at which it releases neurotransmitter onto another neuron. Eventually, however, the stimulation of a sensory cell is always coded as a change in firing of action potentials in a sensory circuit.

Sensory receptor proteins act on ion channels

Sensory receptor proteins respond to stimuli by directly or indirectly opening or closing ion channels in the sensory cell (**Figure 45.2**), leading either to an action potential or to the release of neurotransmitter. Those sensory receptor proteins that act directly on membrane potential are either ion channels themselves or directly affect the opening of an associated ion channel. Examples are receptors that respond to physical force (mechanoreceptors) and those that respond to temperature (thermoreceptors). Electroreceptors do not have receptor proteins, but their cell membranes are sensitive to voltage changes and respond to depolarization by opening voltage-gated Ca^{2+} channels, and the Ca^{2+} triggers neurotransmitter release. Sensory receptor proteins that influence ion channels indirectly usually do so by activating G proteins and second messengers, as described in [Key Concepts 7.2](#) and [7.3](#). Examples are most chemoreceptors and photoreceptors.

Figure 45.2 Sensory Cell Membrane Receptor Proteins Respond to Stimuli

Mechanoreceptors and thermoreceptors have transmembrane proteins that are also cation channels. Changes in their respective stimuli, pressure or heat, alter the permeability of the channels. Electroreceptors are ion channels responsive to electric currents. Chemoreceptors and photoreceptors influence ion channels through G proteins and second messengers.

A recently discovered superfamily of receptor proteins is the focus of considerable research in an effort to identify the molecular mechanisms by which infrared signals are detected. Transient receptor potential (TRP) channel proteins generate a large initial response to a stimulus and then gradually fade even as the stimulus remains constant. Seven classes of TRP channels have been identified, along with about 28 different molecular structures. Each type of TRP channel is specialized to respond to a different stimulus, such as stretch, pressure, temperature, light, and certain chemicals. Some respond to both physical and chemical stimuli, such as one that responds to heat, capsaicin (an active ingredient in chili peppers), and wasabi. Could a heat-sensitive TRP channel be responsible for the infrared-detection function of the pit organs of rattlesnakes? You will pursue this question in **Investigating Life: How Do Pit Vipers “See” in the Dark?**

Sensation depends on which neurons receive action potentials from sensory cells

All sensory systems process information in the form of action potentials. But the sensations we perceive—heat, pressure, light, smell, sound—differ because the messages from different kinds of sensory cells arrive at different places in the CNS. Action potentials arriving in the visual cortex of the brain are interpreted as light, whereas those that arrive in the olfactory bulb are perceived as smells.

A small patch of skin on your arm contains some sensory receptor cells that increase their

firing rates when the skin is warmed and others that increase their activity when the skin is cooled. Other sensory cells in the same patch of skin respond to touch, irritants such as insect bites, and painful stimuli. These receptor cells transmit their messages through axons that enter the CNS at the spinal cord. The synapses made by those axons in the spinal cord and the subsequent pathways of transmission determine whether the stimulation of the skin on your arm is perceived as warmth, cold, touch, itch, or pain; even though the action potentials carried by all of these sensory axons are the same, the connectivity of each axon is specific for a given sensory modality. The *intensity* of a given sensation is coded by the frequency of the action potentials.

Some sensory receptors transmit information about the body's internal conditions of which we are not consciously aware. The brain continuously receives information about body temperature, the concentrations of carbon dioxide and oxygen in the blood, arterial pressure, muscle tension, and the position of the limbs. All of this information is important for homeostasis but does not necessarily result in conscious sensation.

Some sensory receptor cells are assembled with other types of cells into [sensory organs](#), such as eyes, ears, and noses, that enhance the ability of sensory cells to collect, filter, and amplify stimuli. [Sensory systems](#) include the sensory cells, their associated organs, and the neural networks that process the information.

sensory organs Structures that convert types of internal or environmental energy into electrical signals used by the nervous system.

sensory system A set of organs and tissues for detecting a stimulus; consists of sensory cells, the associated structures, and the neural networks that process the information.

Many receptors adapt to repeated stimulation

Some sensory receptor cells give gradually diminishing responses to maintained or repeated stimulation. This phenomenon, known as [sensory adaptation](#), enables an animal to ignore background or unchanging conditions while remaining sensitive to changes and new information. (Note that this use of the term “adaptation” is different from its application in an evolutionary context.) When you get dressed, you feel each item of clothing touch your skin, but the sensation of clothes touching your skin is not constantly on your mind throughout the day. You are immediately aware of new sensations, however, such as your shoe coming untied or someone touching your back.

sensor Cell that is responsive to a particular type of physical or chemical stimulation.

Some sensory receptor cells adapt very little or very slowly; examples are some types of pain receptors and the mechanoreceptors that control balance. You do not want to ignore pain, which usually is signaling that something is wrong in your body, and to maintain equilibrium you must continuously know (albeit unconsciously) the tensions and forces on all of your joints and muscles.

experiment

Original Paper: Gracheva, E. O. et al. 2010. Molecular basis of infrared detection by snakes. *Nature* 464: 1006–1012.

Neurons of the pit organ have their cell bodies in a neural ganglion in the head—the trigeminal ganglion (TG). Sensory neurons conducting information from the body of the snake have their cell bodies in neural ganglia associated with the spinal cord—the dorsal root ganglia (DRGs). Any receptor protein that is involved in sensing heat by the pit organ or by temperature sensors in the skin should be expressed in the TG or the DRGs, respectively.

HYPOTHESIS ▶ Different transient receptor potential (TRP) channel proteins responsive to heat are expressed in the TG and the DRGs, and they have different properties.

METHOD

Many neurons in the TG of rattlesnakes innervate the pit organs, and therefore the RNA transcripts for any protein that is abundant in the pit organ nerve endings should be highly expressed in the TG. Similarly, RNA transcripts for sensory receptor proteins in the skin of the body should be highly expressed in the DRGs. Whole genome RNA sequencing (RNA-seq) was used to create the RNA profiles of the TG and the DRGs of the rattlesnake. Of particular interest were specific TRP RNA reads (specific RNA sequences) that were differentially expressed in the TG and the DRGs. If there are more reads for a certain TRP channel in the TG versus the DRGs, that TRP channel might play a role in the pit organ's ability to sense infrared radiation. Because the range of read values was so large, the data are plotted as logarithmic values (log-log plot).

RESULTS

CONCLUSIONS

1. TRPV1 and "Other TRPs" are expressed equally in the TG and the DRGs, so they probably are not responsible for the unique infrared-sensing properties of the pit organ.
2. TRPA1 is expressed more in the TG than in the DRGs. This channel could therefore serve a unique function in the pit organ.

work with the data

The data from the experiment comparing TRP channel expression in the TG and the DRGs support the conclusion that the TRPA1 channel could be the infrared (IR) sensor in the pit organ. Another piece of evidence would be finding that the *TRPA1* gene is not highly expressed in the TG of snakes without pit organs, or that it is highly expressed in snakes not closely related to rattlesnakes but that have pit organs. Accordingly, the investigators performed RNA-seq analysis of the TG and the DRGs of rat snakes (no pits) and pythons (pits).

RESULTS

(Simulated data, arbitrary units)

Channel	Rat snake		Python	
	TG	DRGs	TG	DRGs
TRPA1	105	110	900,000	50
TRPV1	85	90	15	9

QUESTIONS

1. Compare the relative expression of TRPV1 and TRPA1 in the TG and the DRGs of the rat snake (no pits) and the python (pits). What is the major difference?
2. Explain how these results do or do not support the conclusion that the TRPA1 channel is the IR sensor in the pit organ.
3. What functional data on the TRPA1 channel would further support the conclusion that TRPA1 is the IR sensor in the pit organ?

A similar **work with the data** exercise may be assigned in **LaunchPad**.

45.1 recap

Sensory receptor cells have receptor proteins that respond to specific stimuli from the external or internal environment by directly or indirectly opening or closing ion channels, causing the generation of action potentials or neurotransmitter release in sensory neurons. How the resulting information is processed and interpreted depends on the neural circuitry that is activated.

learning outcomes

You should be able to:

- Describe the roles of receptor potentials and action potentials in sensory systems.
 - Explain how the same membrane event, an action potential, can result in sensations of heat, light, sound, touch, or taste.
 - Describe the various ways that environmental stimuli can generate receptor potentials.
 - Explain the functional significance of sensory adaptation.
-

1. In the crayfish stretch receptor, what creates the receptor potential? Where and how does it stimulate an action
 2. How are we able to perceive action potentials— all of which are essentially the same—as different sensations?
 3. Peppers have a distinctive flavor, but they also can be hot if they contain the molecule capsaicin. Explain the difference in how the flavor versus the hotness of a pepper is sensed.
 4. Why is adaptation or the lack thereof important in different sensory modalities?
-

Now that you have a general view of how sensory systems code and process information, you will next learn how sensory systems gather and filter stimuli, transduce specific stimuli into action potentials, and transmit action potentials to the CNS, which perceives them as different types of information.

45.2 Chemoreceptors Respond to Specific Molecules

A colony of corals responds to a small amount of meat extract in seawater by extending its coral polyps and their tentacles in search of food; a solution of a single type of amino acid can stimulate this response. Conversely, a small amount of seawater in which corals were crushed will stimulate a defensive retraction of the coral polyps. Humans also react strongly to certain chemical stimuli. When you smell freshly baked bread you salivate and feel hungry, and when you smell rotting meat you feel nauseated.

focus your learning

Many different chemoreceptors can be activated in different combinations and to different degrees, enabling discrimination of an enormous number of odorant and pheromone molecules.

Five classes of taste chemoreceptors have different mechanisms of membrane depolarization.

All animals receive information about chemical stimuli through **chemoreceptors**, which are receptor proteins that bind to specific molecules—their **ligands**—and are responsible for smell and taste. Chemoreceptors are also responsible for monitoring some aspects of the internal environment, such as the level of carbon dioxide in the blood.

chemoreceptor A receptor protein that binds to specific molecules (such as odorant molecules or pheromones) in the environment.

ligand (lig' and) Any molecule that binds to a receptor site of another (usually larger) molecule.

Olfaction is the sense of smell

The sense of smell, **olfaction**, depends on chemoreceptors. In vertebrates the olfactory receptors are neurons embedded in a layer of epithelial tissue in the uppermost region of the nasal cavity (**Figure 45.3**). The dendrites of these neurons project as olfactory cilia on the surface of the nasal epithelium, and their axons extend through holes in the overlying bone into the **olfactory bulb** (the olfactory integration area of the brain). A protective layer of mucus covers the nasal cavity epithelium. Molecules from the environment must diffuse through this mucus to reach the receptor proteins on the olfactory cilia. When you have a cold, the amount of mucus in your nose increases, and the epithelium swells. With this in mind, you can easily understand why respiratory infections can cause you to lose your sense of smell.

olfaction (ole fak' shun) [L. *olfacere*: to smell] The sense of smell.

olfactory bulb Structure in the vertebrate forebrain that receives and processes input from olfactory receptor neurons.

Figure 45.3 Olfactory Receptors Communicate Information Directly to the Brain
The receptor cells of the human olfactory system are embedded in epithelial tissues lining the nasal cavity and send their axons to the olfactory bulb of the brain.

An **odorant** is a molecule in the environment that binds to and activates an olfactory receptor protein on the cilia of **olfactory receptor neurons (ORNs)**. Different olfactory receptor proteins bind specific subsets of odorant molecules. An odorant molecule binding to its receptor on an ORN activates a ***G protein**. The G protein then activates an enzyme that causes an increase of a second messenger (cAMP in vertebrates) in the cytoplasm. The second messenger binds to and opens cation channels in the ORN's cell membrane, causing an influx of Na^+ into the ORN—which then depolarizes to threshold and fires action potentials. An interesting feature of ORNs is that they are continuously regenerated. Because they are embedded in nasal epithelium that, like other epithelial linings, is regularly shed, ORNs have to be constantly replaced.

odorant A molecule that can bind to an olfactory receptor.

olfactory receptor neurons (ORNs) Neurons with receptors for different odorants.

The olfactory world has an enormous number of odors and a correspondingly large number of olfactory receptor proteins. In the 1990s Linda Buck and Richard Axel discovered a family of about 1,000 genes in mice (about 3 percent of the mouse genome) that code for olfactory receptor proteins. Each receptor protein that is expressed is found in a limited number of ORNs in the olfactory epithelium, and each ORN expresses just one receptor type. The investigators matched specific gene products with the odorants they detect. For their discoveries of the molecular nature of the olfactory system, Buck and Axel received a Nobel Prize in 2004.

Olfactory sensitivity enables discrimination of many more odorants than there are olfactory receptors. An odorant molecule can be quite complex, and different regions of that molecule may bind to different receptor proteins. The next stage of processing olfactory information is in the olfactory bulb, where axons from ORNs expressing the same receptor protein cluster together on olfactory bulb neurons, forming structures called glomeruli (see [Figure 45.3](#)). A complex odorant molecule can activate a unique combination of glomeruli in the olfactory bulb, so an olfactory system with hundreds of different receptor proteins can discriminate an astronomically large number of smells. The more odorant molecules that bind to ORNs, the greater the frequency of action potentials and thus the greater the intensity of the perceived smell.

Humans have a sensitive olfactory system, but in comparison with most mammals we depend far more on vision than on olfaction. The nasal epithelium of a typical dog is 15-20 times larger

than a human's and has about *300 million* odorant receptors, compared with about 6 million in the average human. For some scents, the threshold sensitivity of the dog is 100,000 times lower; a dog's nose reveals a huge amount of information not available to people.

Some chemoreceptors detect pheromones

A specialized type of chemical signal used for communication among conspecifics (individuals of the same species) is called a **pheromone**. Individual animals secrete pheromone molecules into the environment, triggering behavioral responses in other individuals of the species.

Pheromones may communicate alarm signals, mark food trails, or define territories, among many other uses. Their function in mating and mate attraction especially illustrates the remarkable sensitivity of chemosensory systems, and the silkworm moth *Bombyx mori* is an extensively studied example.

pheromone (feer' o mone) [Gk. *pheros*: carry + *hormon*: excite, arouse] A chemical substance used in communication between organisms of the same species.

To attract a mate, the female silkworm moth releases a phero- mone called bombykol from a gland at the tip of her abdomen (**Figure 45.4A**). The male silkworm moth has about 10,000 receptors for this molecule on each of his feathery antennae (**Figure 45.4B**). A single molecule of bombykol may be sufficient to generate action potentials in the antennal nerve, which transmits the signal to the male's CNS. The extreme sensitivity of the male bombykol receptors ensures that the sexual message sent by a female moth is likely to reach any male within a huge downwind area. The rate of firing in the male's sensory nerves is proportional to the concentration of bombykol in the air, so by flying upwind he can follow an airborne concentration gradient to "home in" on the signaling female.

(A) Release of pheromone by female

(B) Detection of pheromone by male

The female moth releases a **pheromone** from a gland at the tip of her abdomen. The pheromone can travel thousands of meters downwind.

A male moth detects this pheromone in the air passing over his antennae, which are covered with chemo-sensitive hairs.

Figure 45.4 Pheromones Can Communicate over Great Distances Mating in silkworm moths of the genus *Bombyx* is coordinated by a pheromone called bombykol.

Q: Molecules have different diffusion coefficients. *Bombykol* has a high diffusion coefficient. How do you think its diffusion coefficient would compare with that of a territory-marking pheromone, and why might they be different?

The vomeronasal organ contains chemoreceptors

The **vomeronasal organ (VNO)** is a small, paired tubular structure embedded in the nasal epithelium of amphibians, reptiles, and many mammals (although not humans). In mammals the VNO is located on the septum dividing the two nostrils (see [Figure 52.3](#)) and has a pore that opens into the nasal cavity. The VNO pulsates and draws a sample of nasal fluid over the chemoreceptors embedded in its walls. The information from these chemoreceptors goes to an accessory olfactory bulb in the brain, and from there to brain regions involved in sexual and other instinctive behaviors. The VNO of a rodent detects pheromones that signal the sex, strain, identity, and sexual receptivity of another individual.

vomeronasal organ (VNO) Chemosensory structure embedded in the nasal epithelium of amphibians, reptiles, and many mammals. Often specialized for detecting pheromones.

In snakes the VNO opens into the roof of the mouth cavity. Each time the snake's forked tongue darts in and out, the forks fit into the VNO openings and present the chemoreceptors located there with a sample of molecules from the surrounding air (see the chapter opening photo). Thus the snake uses its tongue to smell its environment, not to taste it. Why doesn't the snake simply use the flow of air to and from its lungs, as we do, to smell the environment? In snakes, air flows to and from the lungs slowly (and can even stop entirely for long periods of time), but the tongue can dart in and out rapidly. It is a quick source of olfactory information used in social communication and hunting prey.

Gustation is the sense of taste

In humans and other vertebrates, the sense of taste, **gustation**, depends on clusters of chemoreceptors called **taste buds**. The taste buds of terrestrial vertebrates are confined to the mouth cavity, but some fish have taste buds in the skin that enhance their ability to sense their environment. Some fish living in murky water are very sensitive to small amounts of amino acids in the water and can find food without the use of vision. The duck-billed platypus, a prototherian mammal (see [Figure 32.26B](#)), has similar talents as a result of taste buds on the sensitive skin of its bill.

gustation The sense of taste.

taste bud A structure in the epithelium of the tongue that includes a cluster of chemoreceptors innervated by sensory neurons.

The human tongue has 5,000-10,000 taste buds embedded in the epithelium. Most of them are found on the sides of the papillae ([Figure 45.5](#)). (Look at your tongue in a mirror—the papillae make it look fuzzy.) The outer surface of a taste bud has a pore that exposes the tips of the sensory receptor cells. Microvilli (tiny hairlike projections) increase the surface area of these cells where their tips converge at the pore. These chemoreceptor cells generate action potentials and release neurotransmitter at their bases, where they form synapses with sensory neurons that convey the signals to the CNS.

Figure 45.5 Taste Buds Are Clusters of Sensory Cells A human tongue has as many as 10,000 taste buds, most of which are found on the raised papillae.

The tongue does a lot of hard work, so its epithelium, along with cells of its taste buds, are shed and replaced at a rapid rate. Individual taste bud cells last about 10 days before they are replaced, but the sensory neurons associated with them live on, constantly forming new synapses as new taste buds form.

Gustation begins with the membrane receptor proteins of the microvilli of the taste bud sensory cells (see [Figure 45.5](#)). Humans perceive five taste classes: sweet, salty, sour, bitter, and umami. However, taste buds can distinguish among a variety of sweet-tasting molecules and a variety of bitter-tasting molecules. Umami is a savory, meaty taste that is stimulated by amino acids, including monosodium glutamate (MSG), a commonly used flavor enhancer. Sweet, bitter, and umami tastes are the functions of a small family of G protein-coupled TRP channels. Other TRP channels related to the ones you saw associated with heat sensation in *Investigating Life: How Do Pit Vipers “See” in the Dark?* are responsible for spicy/hot tastes. Still other TRP channels that act as cold sensors are activated by minty, cool-tasting foods. Saltiness receptor proteins allow Na^+ to diffuse into taste bud sensory cells through open Na^+ channels, depolarizing the sensory cell. Sourness receptors are activated by a direct effect of H^+ ions on Na^+ channels.

s

Various selective pressures led to the evolution of diversity in gustatory receptors. Receptors for bitter tastes may have evolved as protective mechanisms enabling animals to detect toxic plant compounds such as quinine, caffeine, and nicotine. Because many such toxic compounds evolved in plants as protections against herbivorous predators, having a variety of receptors in those herbivores is a product of the continuous “arms race” between predators and prey (see [Key Concept 55.1](#)). Also, a large number of molecules in food could indicate nutritional value, so a variety of receptors is of value. The diversity of sweet receptors helps explain why it has been possible to invent many chemically distinct artificial sweeteners.

Regardless of the mechanism of taste transduction by the receptors of the taste buds, all these cells release neurotransmitter onto sensory neurons. These neurons then generate action potentials that are conducted to the CNS, where they are interpreted as specific taste sensations. The full complexity of the chemosensitivity that enables us to enjoy the subtle

flavors of food comes from the combined activation of gustatory and olfactory receptors, which is why you may lose your sense of taste when you have a cold.

45.2 recap

All animals receive information about chemical stimuli through chemoreceptors, which have diverse structures and bind to a tremendous variety of ligands. Chemoreceptors are the basis of the sensations of olfaction and gustation and the reception of pheromones. They also monitor some aspects of an animal's internal environment.

learning outcomes

You should be able to:

- Describe how a large but limited number of olfactory receptor proteins can discriminate a much larger number of odorant molecules, as well as their concentrations.
 - Explain how the five classes of taste receptors generate action potentials in their sensory neurons.
-
1. Different odorants have different cell surface receptors, but these receptors activate the same intracellular G protein signaling pathway. How does the olfactory system discriminate different odors?
 2. How does the olfactory system discriminate between the whiff of a skunk, a repulsive odor of skunk, and the smell of a skunk cabbage?
 3. The concentration thresholds for sensing bitter tastes are lower than for salt or sweet. Offer an evolutionary explanation for why this is so.
 4. With only five classes of taste receptors, how can we discriminate so many different tastes?

You have now seen how chemoreceptors give rise to the sensations of smell and taste, and how some animals use chemoreception to communicate with others of their species. Next we describe the sensory cells that respond to mechanical forces, including the vibrations you perceive as sound.

***connect the concepts** * connect the concepts [Key Concept 7.2](#) describes how G protein-linked receptors transmit signals from a variety of stimuli outside a cell to its interior. Ligand binding of the receptor activates the G protein on the cytoplasmic surface of the membrane, which — if bound by GTP—will activate an effector.

45.3 Mechanoreceptors Respond to Physical Forces

The cell membranes of [mechanoreceptors](#) have cation channels that open when the membrane is disturbed by physical forces. The intensity of the physical force is registered as a graded receptor potential, which in turn leads to either the release of neurotransmitter or the generation of action potentials. The amount of neurotransmitter release or the rate of action potentials tells the CNS the strength of the stimulus to the mechanoreceptor. A diversity of mechanoreceptor cells has evolved in different sensory systems. The functions of these cells range from interpreting skin sensations to sensing blood pressure to hearing and maintaining balance.

mechanoreceptor A cell that is sensitive to physical movement and generates action potentials in response.

focus your learning

A variety of pressure-sensitive receptors enable multiple modes of mechanosensation.

Stretch receptors in muscle spindles signal for contraction, and stretch receptors in tendons signal for relaxation.

As the frequency of the sound stimulus decreases, the stimulated region of the basilar membrane moves from basal to apical.

The ear converts sound waves in air to pressure waves in fluid that bend hair cells to create auditory sensation.

Many different receptor cells respond to touch and pressure

Human skin (and that of other mammals) is packed with diverse mechanoreceptors that generate varied sensations ([Figure 45.6](#)). The most important tactile receptors, found in both hairy and non-hairy skin, are [Merkel's discs](#), which adapt rather slowly and provide continuous information about anything touching the skin. [Meissner's corpuscles](#), found primarily in non-hairy skin, are very sensitive but adapt rapidly; they provide information about *changes* in things touching the skin. The rapid adaptation of Meissner's corpuscles is why you roll a small object between your fingers (rather than holding it still) to discern its shape and texture: as you roll it, the object continually stimulates Meissner's corpuscles.

Merkel's discs Slowly adapting skin mechanoreceptors that provide continuous information about anything touching the skin.

Meissner's corpuscles Rapidly adapting skin mechanoreceptors sensitive to light touch and vibration. Found primarily in non-hairy skin; provide continuous information about changes in things touching the skin.

Figure 45.6 The Skin Feels Many Sensations Even a very small patch of skin contains a variety of sensory cells, making the skin a multimodal receptor that can sense temperature, pressure, texture, pain, touch, and itch.

Deeper in the skin, **Ruffini endings** adapt slowly and are good at providing information about vibrating stimuli of low frequencies, while **Pacinian corpuscles**, which adapt rapidly, provide information about vibrating stimuli of higher frequencies. Even deeper in the skin, the dendrites of sensory neurons wrap around hair follicles. When the surface hairs are displaced, those neurons are stimulated.

Ruffini endings Slowly adapting stretch receptor in the skin.

Pacinian corpuscles (puh sin' ee uhn) Encapsulated mechanoreceptors in deep skin sensitive to pressure and vibration.

The density of tactile mechanoreceptor cells varies across the body's surface. By touching the skin with two toothpicks simultaneously (when a person's eyes are closed!), you can determine

how far apart two stimuli have to be before the person can tell whether the sensations are produced by one toothpick or by two. On back skin, stimuli have to be relatively far apart before they are perceived as two discrete stimuli. But when this same “two-point spatial discrimination test” is applied to the lips or fingertips, a person can identify two stimuli as separate even when they are quite close together, because the receptor density is much greater in these regions.

Mechanoreceptors are also found in muscles, tendons, and ligaments

An animal receives information from mechanoreceptors about the position of its limbs and the stresses on its muscles and joints. These mechanoreceptors supply information continuously to the CNS, and this information is essential for postural control and the coordination of movements.

The mechanoreceptors in skeletal muscle are the [muscle spindles](#). These stretch receptors are modified muscle cells embedded in connective tissue inside muscles and innervated by sensory neurons ([Figure 45.7A](#)). When a muscle is stretched, the [muscle spindles](#) are stretched as well, signaling the spindle neurons to transmit action potentials to the CNS. [Figure 45.1](#) showed how crayfish stretch receptors transduce physical force into action potentials; the actions of muscle spindles are similar. The CNS uses the information from muscle spindles to adjust the strength of the muscle contraction so that it matches the load put on the muscle; thus a person can hold a mug steady while it is being filled.

muscle spindles Mechanoreceptors embedded in skeletal muscle that sense changes in the length of the muscle.

muscle spindles Mechanoreceptors embedded in skeletal muscle that sense changes in the length of the muscle.

Figure 45.7 Stretch Receptors Stretch receptors provide information about the stresses on muscles and joints in an animal's limbs. (A) Signals from muscle spindles to the CNS initiate muscle contraction. (B) Golgi tendon organs in tendons and ligaments inhibit a contraction that becomes too forceful, triggering a reduction in muscle tension and protecting the muscle from tearing.

Another type of mechanoreceptor, the **Golgi tendon organ**, is found in tendons and ligaments and provides information about the force generated by a contracting muscle (**Figure 45.7B**). When a contraction becomes too forceful, action potentials from the Golgi tendon organ inhibit the spinal cord motor neurons innervating that muscle, causing the muscle to relax and protecting it from tearing. (You may recall a cell organelle called the Golgi apparatus. What these two very different structures have in common is their discovery in the late nineteenth century by the Italian anatomist Camillo Golgi.)

Golgi tendon organ A mechanoreceptor found in tendons and ligaments; provides information about the force generated by a contracting muscle.

Hair cells are mechanoreceptors of the auditory and vestibular systems

Hair cells are the mechanoreceptors for the vertebrate auditory (sound-perceiving) and vestibular (equilibrium-maintaining) systems. Both of these systems are housed in the complex structures of the vertebrate ear. **Stereocilia**—fingerlike extensions of the cell membrane

stiffened by cross-linked actin filaments—project from the surface of each hair cell like a set of organ pipes (**Figure 45.8**). Stereocilia bend in response to waves of pressure; bending of the stereocilia in one direction depolarizes the hair cell, and bending in the other direction hyperpolarizes it.

hair cell A type of mechanoreceptor in animals. Detects sound waves and other forms of motion in air or water.

stereocilia Fingerlike extensions of hair cell membranes whose bending initiates sound perception. (See hair cell.)

Figure 45.8 Hair Cells Have Mechanosensors on Their Stereocilia Hair cells have stereocilia that are connected with each other by small filaments. When a cilium is bent in one direction, the filament opens a cation channel at the tip of the neighboring cilium, resulting in depolarization of membrane potential. When depolarized, the hair cell releases neurotransmitter onto a sensory neuron. Movement of the hair cell in the opposite direction closes the cation channel and the cell hyperpolarizes, causing a reduction in its release of neurotransmitter.

Measurements with microelectrodes have shown that the bending of stereocilia creates local electric currents near their tips, indicating that ion channels near the tips must be opening or closing. Electron microscope images reveal minute filaments that connect the tip of each stereocilium to its taller neighbor. It is hypothesized that these filaments are fine molecular attachments to the ion channels, and that they act like springs that open the channels. If the taller neighboring stereocilium is bent away, the spring tightens and the ion channel is opened. If the taller neighbor bends toward its shorter neighbor, the spring is relaxed and the channel closes (see [Figure 45.8](#)).

Auditory systems use hair cells to sense sound waves

The stimuli that animals perceive as sounds are pressure waves. Auditory systems use mechanoreceptors to convert pressure waves into receptor potentials. Auditory systems include special structures that gather sound waves, direct them to the sensory organ, and amplify their effect on the mechanoreceptors. A good example of an auditory system is the human ear (**Focus: Key Figure 45.9**), which can be divided into three major areas: the outer, middle, and inner ear (see [Figure 45.9A](#)).

focus: key figure

(A) Overview of the human auditory system

(B) The middle and inner ear

(C) Cross section of the cochlea

(D) The organ of Corti

Figure 45.9 Structures of the Human Ear (A) The pinnae direct sound waves down the auditory canal to impinge on the tympanic membrane. The tympanic membrane mechanically transmits these pressure waves into movements of the ossicles in the middle ear. (B) The ossicles transmit their movement into pressure waves in the fluid of the cochlea at the oval window. (C) The cochlea is divided into fluid-filled canals; pressure waves from the ossicles cause the membranes between the canals to flex. (D) Flexing of the basilar membrane bends stereocilia on hair cells in the organ of Corti.

Q: How can the ears detect directionality of a sound source?

OUTER EAR

The outer ear consists of the pinnae (singular, pinna) and the auditory canal. The pinnae collect sound waves and direct them into the auditory canals; watch a dog change the orientation of its ears to focus on a particular sound to get the idea of the role pinnae play in hearing. Covering the end of the auditory canal is the **tympanic membrane** (commonly called the eardrum) which vibrates in response to pressure waves traveling down the canal, thus converting the pressure waves to physical forces in the middle ear.

tympanic membrane [Gk. *tympanum*: drum] The eardrum.

MIDDLE EAR

On the other side of the tympanic membrane is the middle ear, an air-filled cavity connected to the throat at the back of the mouth through the **eustachian tube** (also called the pharyngotympanic tube). Because the eustachian tube is also filled with air, pressure can equilibrate between the middle ear and the environment. When you have a cold, the tube can be blocked by mucus or tissue swelling and you may have difficulty equilibrating the pressure in the middle ear with the outside air pressure (as you have to do when changing altitude in an airplane).

eustachian tube A connection between the middle ear and the throat that allows air pressure to equilibrate between the middle ear and the outside world. Also called the pharyngotympanic tube.

The middle ear contains the **ossicles**, three delicate bones individually named the malleus (“hammer”), incus (“anvil”), and stapes (“stirrup”) (see [Figure 45.9B](#)). The ossicles transmit the vibrations of the tympanic membrane to another flexible membrane, the **oval window**. The ossicles act as a lever (like a hammer pulling out a nail), translating a large movement of the tympanic membrane into a smaller movement of the oval window, but a movement of greater force. Because the oval window is much smaller than the tympanic membrane, the pressure the stapes transmits to the oval window is more than 20 times greater than the pressure exerted by a sound wave on the tympanic membrane.

ossicles Three bones in the middle ear that transmit vibrations from tympanum to the oval window of the inner ear. Individually named the malleus (“hammer”), incus (“anvil”), and stapes (“stirrup”).

oval window The flexible membrane that, when moved by the bones of the middle ear, produces pressure waves in the inner ear.

Behind the oval window lies the fluid-filled inner ear. Movements of the oval window impart pressure changes to that enclosed fluid. These pressure waves are transduced into action potentials.

INNER EAR

The inner ear is a bony structure consisting of two sets of canals. One is the organ of balance, the **vestibular system**, and the other is the organ of hearing, the **cochlea**. The cochlea (“snail” or “spiral shell”) is a long, tapered, coiled structure. A cross section of the cochlea reveals that it is composed of three parallel canals separated by two membranes, the vestibular membrane and the basilar membrane (see [Figure 45.9C](#)). Sitting on the basilar membrane is the **organ of Corti**, which transduces pressure waves into action potentials. The organ of Corti contains hair cells with stereocilia (see [Figure 45.8](#)). The tips of the hair cells are embedded in a gelatinous overhanging shelf called the tectorial membrane (see [Figure 45.9D](#)).

vestibular system (ves tib’ yew lar) [L. *vestibulum*: an enclosed passage] Structures within the inner ear that sense changes in position or momentum of the head, affecting balance and motor skills.

cochlea (kock’ lee uh) [Gk. *kokhlos*: snail] A spiral tube in the inner ear of vertebrates; it contains the sensory cells involved in hearing.

organ of Corti Structure in the inner ear that transforms mechanical forces produced from pressure waves (“sound waves”) into action potentials that are sensed as sound.

Stereocilia are not motile, but because their tips are attached to the more rigid tectorial membrane, stereocilia bend when the basilar membrane flexes. As shown in [Figure 45.8](#), when the stereocilia are bent in one direction, the hair cell is depolarized by an inflow of K⁺ ions. This effect of opening K⁺ channels happens because the fluid in the cochlear canal has a higher K⁺ concentration than does the intracellular fluid of the hair cell. The response of the hair cell is a graded membrane potential. The hair cells do not fire action potentials, but the changes in their membrane potential alter the rate at which the hair cells release neurotransmitter onto the sensory neurons whose axons make up the auditory nerve and transmit action potentials to the brain.

The vestibular and tympanic canals are separate until they reach the distal end of the cochlea (the end farthest from the oval window), where they join; thus they form one continuous canal that turns back on itself (see [Figure 45.10](#)). Just as the oval window is a flexible membrane at the beginning of the vestibular canal, the **round window** is a flexible membrane at the end of the tympanic canal. When the oval window vibrates, the waves of fluid pressure create traveling waves of flexion in the basilar membrane.

round window A flexible membrane at the end of the lower canal of the cochlea in the human ear. (See also oval window.)

Flexion of the basilar membrane is perceived as sound

What causes the basilar membrane to flex, and how does this mechanism distinguish sounds of different frequencies? Air is highly compressible but fluids are not; therefore a pressure wave can travel through air without displacing much air, whereas a pressure wave in fluid displaces that fluid. When the stapes pushes on the oval window, the fluid in the vestibular canal is displaced. If the movement of the oval window occurs slowly, the cochlear fluid pressure wave travels down the vestibular canal, around the bend, and back through the tympanic canal ([Figure 45.10](#)). At the end of the tympanic canal, the displacement pressure is dissipated by the outward bulging of the round window.

Hypothetical uncoiling of cochlea

Pressure waves vibrate tympanic membrane and ossicles.

Low pitch: Pressure waves travel far down the vestibular canal and flex the basilar membrane, activating action potentials in low-frequency sensors.

Medium pitch: Pressure waves travel only part of the way down the upper canal before flexing the basilar membrane and activating mid-frequency sensors.

High pitch: Pressure waves travel a short distance before flexing the basilar membrane and activating high-frequency sensors.

Figure 45.10 Sensing Pressure Waves in the Inner Ear Pressure waves of different frequencies flex the basilar membrane at different locations. Information about sound frequency is specified by which hair cells are activated. For simplicity, this representation illustrates the cochlea as uncoiled.

Animation 45.1 **Sound Transduction in the Human Ear** www.Life11e.com/a45.1.

The basilar membrane is not uniform — it is thicker and stiffer at its base and wider and thinner at its apical end. Pressure waves in the cochlear fluid have different frequencies and set up different patterns of traveling waves. High-frequency waves cause maximal flexion at the basal end of the basilar membrane, whereas low-frequency pressure waves result in maximal flexion at the apical end (see [Figure 45.10](#)). Thus different pitches of sound flex the basilar membrane at different locations and activate different sets of hair cells. Action potentials stimulated by the mechanoreceptors at different positions along the organ of Corti travel along the cochlear nerve and are transmitted to different regions of the brain's auditory cortex by the vestibulocochlear nerve.

Various types of damage can result in hearing loss

There are two general types of acquired hearing loss, or deafness. Conduction deafness is caused by the loss of function of the tympanic membrane and/or the ossicles of the middle ear. Repeated infections of the middle ear can cause scarring of the tympanic membrane and stiffening of the connections between the ossicles. The consequence is less efficient conduction of sound waves from the tympanic membrane to the oval window. With increasing age, the ossicles inevitably stiffen, resulting in a gradual loss of the ability to hear high-frequency sounds.

Nerve deafness is caused by damage to the inner ear or the auditory pathways. A common cause of nerve deafness is damage to the hair cells of the delicate organ of Corti by exposure to loud sounds such as jet engines, pneumatic drills, or highly amplified music. Consistent exposure to sounds above 85 decibels can damage hearing; this damage is cumulative and irreversible. Even using earphones can put you at risk for hearing loss because they generate high-pressure sound waves close to the tympanic membrane. Personal stereo earphones can reach 120 decibels, and people commonly use them at 100 decibels (equivalent to being at a rock concert).

The vestibular system uses hair cells to detect forces of gravity and momentum

Hair cells in the vestibular system of the inner ear detect the position and movement of the head — information essential for maintaining equilibrium (balance). Information from the vestibular system is also crucial for the control of eye movements. When you look at something, you can move your head while staying focused on the object because of your vestibulo-ocular reflex.

In the mammalian inner ear, the vestibular system consists of three bony [semicircular canals](#) and a bony chamber called the [vestibule](#). Within each canal is a membranous semicircular duct, and within the vestibule are the membranous saccule and the utricle. The ducts and the saccule and utricle are filled with fluid. In the semicircular ducts, the fluid shifts when the head changes position ([Figure 45.11A](#)). Since the three semicircular canals have different orientations, the fluid in their ducts responds differentially to the direction of movement. Projecting into the base of each duct is a [cupula](#), a gelatinous swelling enclosing a cluster of hair cell stereocilia. When the shifting fluid pushes on the cupula, it bends the stereocilia and causes a graded potential in the hair cell membranes.

semicircular canals Three canals in the human inner ear that form part of the vestibular system.

vestibule A central part of the inner ear involved in balance.

cupula Gelatinous swelling in the semicircular canals of the vestibular system. A cupula encloses hair cell stereocilia that react to shifting fluid in the canal ducts.

(A) Looking through a semicircular canal to the cupula

(B) Stereocilia dynamics in the saccule and utricle

Figure 45.11 Organs of Equilibrium The vestibular system consists of bony chambers and fluid-filled canals. **(A)** Each semicircular duct has a cupula containing stereocilia. When fluid moves against the cupula, the stereocilia bend. **(B)** In the saccule and utricle, stereocilia are bent by gravitational forces on the otoliths.

The stereocilia in the saccule and utricle are bent in a different way. These stereocilia are embedded in gelatinous membranes that contain **otoliths** ("ear stones") which are crystals of calcium carbonate. When the head changes position or when it accelerates or decelerates, gravitational forces are exerted on the otoliths and the stereocilia bend (**Figure 45.11B**).

otoliths (oh' teliths) [Gk. *ous*: ear + *lithos*: stones] Crystals of calcium carbonate in the inner ear. Also called ear stones.

As in the cochlea, the hair cells of the vestibular system do not fire action potentials, but they release neurotransmitter at synapses With sensory neurons, which in turn fire action potentials.

Motion sickness is a common malady experienced as seasickness or car sickness. This condition occurs when the vestibular system and the visual system produce conflicting information. The vestibular system may be indicating movement when the visual system is not, or vice versa.

45.3 recap

Sensations that derive from mechanoreceptors include touch, tickle, pressure, joint position, muscle load, hearing, and equilibrium. The membranes of mechanoreceptors have ion channels that are opened by distortion of the membrane, resulting in graded receptor potentials that cause the cell to release neurotransmitter or to fire action potentials. Hair cells involved in hearing and equilibrium have stereocilia that are bent by pressure waves, resulting in receptor potentials.

learning outcomes

You should be able to:

- Describe the various touch sensors and their unique properties.
- Describe how tension in a muscle is sensed and adjusted for load.
- Explain how sound waves of different frequencies are heard as sounds of different pitches.

-
1. Why are there different types of mechanoreceptor cells that have different rates of adaptation?
 2. Explain the role of specific mechanoreceptors when you are (a) holding a glass that is being filled and (b) lifting heavy furniture.
 3. How do different frequencies of pressure waves in the air result in action potentials being fired in different acoustic neurons?

We next turn to vision, perhaps the most elaborate of the senses.

45.4 Photoreceptors Respond to Light

Sensitivity to light—**photosensitivity**—confers on the simplest animals the ability to orient to the sun and sky, and it gives more complex animals rapid and extremely detailed information about objects in their environment. Photosensitivity is ubiquitous in the animal kingdom, and the molecular basis for that sensitivity is a family of visual pigments that have been evolutionarily conserved.

photosensitivity Sensitivity to light.

focus your learning

Rhodopsin transduces light energy into changes in membrane potential.

Vertebrate rods are sensitive to light with high sensitivity; cones are sensitive to color.

Receptive fields of photoreceptors send their output to ganglion cells along with lateral processing by horizontal and amacrine cells, enabling motion and contrast detection.

In this section you will learn about the structures of eyes, the organs that gather light energy and focus it onto **photoreceptor cells**. Then you will learn how visual pigment molecules of photoreceptors respond when stimulated by light energy and the molecular mechanism that transforms that light energy into action potentials. You will also learn about color vision and how photoreceptor information is processed in the neural layers of the vertebrate eye.

Animation 45.2 **Photosensitivity** www.Life11e.com/a45.2

photosensitivity Sensitivity to light.

Invertebrates have a variety of visual systems

Photoreceptors and visual pigments are incorporated into a variety of visual systems, from simple to complex. Flatworms obtain directional information about light from photoreceptor cells that are organized into **eye cups**. The eye cups are paired, bilateral structures, each partly shielded from light by a layer of pigmented cells lining the cup.

The photoreceptors on the two sides of the animal are unequally stimulated unless the animal is facing directly toward or away from a light source. The flatworm generally uses directional information from the eye cups to move away from light.

Arthropods have **compound eyes** that provide them with information about patterns in the environment. These eyes are called compound because each eye consists of many optical units called **ommatidia** (singular *ommatidium*), each with its own narrow-angle lens (**Figure 45.12**). In contrast, a vertebrate eye consists of just one optical unit with a wide-angle lens. The number of ommatidia in a compound eye varies from only a few in some ants to 800 in fruit flies and to 30,000 in some dragonflies.

ommatidia [Gk. *omma*: eye] The units that make up the compound eye of some arthropods.

Figure 45.12 Ommatidia: The Functional Units of Insect Eyes (A) The micrograph shows the compound eye of a fruit fly. (B) The rhodopsin-containing retinula cells are the photoreceptors in ommatidia.

Each ommatidium has a lens that directs light onto photoreceptor cells. Flies, for example, have eight elongated photoreceptors in each ommatidium. The inner borders of the photoreceptors are covered with microvilli that contain a photosensitive pigment that traps light. Axons from the photoreceptors send the light information to the nervous system. Since each ommatidium of a compound eye is directed at a slightly different part of the visual world, only a low-resolution (pixillated) image can be communicated from the compound eye to the CNS.

Image-forming eyes evolved independently in vertebrates and cephalopods

Both vertebrates and cephalopod mollusks (such as squid and octopus) have eyes with exceptional abilities to form detailed images of the visual world. Like cameras, both of these eye types focus inverted images on an internal surface that is sensitive to light. Considering that they evolved completely independently of each other, their degree of similarity is remarkable (**Figure 45.13**).

Figure 45.13 Convergent Evolution of Eyes The lenses of vertebrate (A) and cephalopod (B) eyes focus images on layers of photoreceptor cells.

Q: Humans commonly experience “floaters” in their eyes—tissue fragments that float around in the field of vision. Where in the structure of the eye would you expect floaters to exist?

The vertebrate eye (see [Figure 45.13A](#)) is a spherical, fluid-filled structure bounded by a tough connective tissue layer called the **sclera**. The sclera at the front of the eye forms the transparent **cornea**, through which light passes to enter the eye. Just inside the cornea is the pigmented **iris**, which gives the eye its color. The iris controls the amount of light that reaches the photoreceptor cells at the back of the eye, just as the diaphragm of a camera controls the exposure. The central opening of the iris is the **pupil**. The iris is under neural control. In bright light, the iris constricts and the pupil is very small. As light levels fall, the iris opens and the pupil enlarges.

sclera The white outer layer of the eyeball continuous with the cornea.

cornea The clear, transparent tissue that covers the eye and allows light to pass through to the retina.

iris (eye’ ris) [Gk. *iris*: rainbow] The round, pigmented membrane that surrounds the pupil of the eye and adjusts its aperture to regulate the amount of light entering the eye.

pupil The opening in the vertebrate eye through which light passes.

Behind the iris is the crystalline protein **lens** that makes fine adjustments in the focus of images falling on the photosensitive layer—the **retina**—at the back of the eye. The cornea and the gel-like mass (vitreous humor) within the eye bend light rays passing through them so that they are focused on the retina. The lens makes fine adjustments to the focus and allows the eye to accommodate—that is, to focus on objects at various locations in the near visual field. To focus a camera on objects close at hand, you adjust the distance between the lens and the internal surface sensitive to light. Fish, amphibians, and non-avian reptiles accommodate in a similar manner, moving the lenses of their eyes closer to or farther from their retinas. Mammals and birds use a different method; they alter the shape of the lens.

lens In the vertebrate eye, a crystalline protein structure that makes fine adjustments in the focus of images falling on the retina.

retina (rett' in uh) [L. *rete*: net] The light-sensitive layer of cells in the vertebrate or cephalopod eye.

The mammalian lens is contained in a connective tissue sheath that tends to keep it in a spherical shape, but the sheath is attached to suspensory ligaments that pull the lens into a flatter shape. Circular ciliary muscles counteract the pull of the suspensory ligaments, permitting the lens to round up. When the ciliary muscles are at rest, the flatter lens has the correct optical properties to focus distant images on the retina. Contracting the ciliary muscles rounds up the lens, changing its light-bending properties to bring close images into focus (**Figure 45.14**).

Figure 45.14 Staying in Focus Mammals and birds focus their eyes by changing the shape of the lens depending on the eye's distance from the object of focus.

Lenses become less elastic with age, so we lose the ability to focus on objects close at hand without the help of corrective lenses. Most people over the age of 45 need the assistance of reading glasses or bifocal lenses.

 Activity 45.3 **Structure of the Human Eye** www.Life11e.com/ac45.3

The vertebrate retina receives and processes visual information

During embryonic development, neural tissue grows out from the brain to form the retina. In addition to a layer of photoreceptor cells, the retina includes other cells arranged in layers that process visual information from the photoreceptors (see **Figure 45.20**). Light must pass through all the layers of retinal cells before being captured by photosensors. In humans and other day-active animals, the light that is not captured is absorbed by a black-pigmented epithelial tissue layer behind the retina. In contrast, nocturnal animals such as deer and raccoons have an iridescent reflective layer behind their retinas, which maximizes the capture of photons by reflecting them back onto the photoreceptors. This is why a deer in the headlights or your pet

dog or cat in a flash photo appears to have bright white eyes. In contrast, humans do not have a white reflective layer in the retina, so flash photographs often have a “red-eye effect,” caused by the flash being reflected by the abundant blood vessels in the retina.

Opsins are the universal photoreceptor molecule in animals

Photosensitivity in animals depends on the ability of [opsin](#) molecules to absorb photons of light and activate a G protein. Opsins are proteins that are not themselves photosensitive, but they contain covalently bound functional groups called 11-*cis*-retinal ([Figure 45.15](#)). Retinal absorbs photons of light, and the color of light it receives depends on the structure of its opsin. There are several different opsins, and the most common one that gives humans sensitivity to low levels of light, but not color, is called [rhodopsin](#).

opsin (op' sin) [Gk. *opsis*: sight] The protein portion of vertebrate visual pigments; associated with the pigment molecule 11-*cis*-retinal. (See *also* rhodopsin.)

rhodopsin A vertebrate visual pigment involved in transducing photons of light into changes in the membrane potential of certain photoreceptor cells.

Figure 45.15 Light Changes the Conformation of Rhodopsin The light-absorbing molecule 11-*cis*-retinal bonds with the protein opsin to form the vertebrate visual pigment rhodopsin.

When 11-*cis*-retinal absorbs a photon of light energy, it changes into a different isomer of retinal, called all-*trans*-retinal. This change puts a strain on the bonds between retinal and opsin, changing the conformation of opsin and signaling the detection of light. In vertebrate eyes, the retinal and the opsin eventually separate from each other (a process called bleaching), which causes the opsin to lose its photosensitivity. A series of enzymatic reactions returns the all-*trans*-retinal to the 11-*cis* isomer, which then recombines with opsin so that it once again becomes photosensitive.

How does the conformational change of opsin transduce light into a cellular response? After retinal is converted from the 11-*cis* to the all-*trans* form, its interactions with opsin pass through several unstable intermediate stages. One of these stages triggers a cascade of reactions involving a G protein signaling mechanism that results in the alteration of membrane potential

that is the photoreceptor cell's response to light.

Rod and cone cells are the photoreceptors of the vertebrate retina

The photoreceptors of the vertebrate retina are two types of modified neurons called **rod cells** and **cone cells** based on their shapes (**Figure 45.16**). Rod cells are highly light-sensitive and perceive shades of gray in dim light. Cone cells function at high light levels and are responsible for high-acuity color vision. The human retina has about 5 million cones and 100 million rods, but the density of each varies across the retina.

rod cells Light-sensitive cells in the vertebrate retina; these sensory receptor cells are sensitive in extremely dim light and are responsible for dim light, black and white vision.

cone cells In the vertebrate retina, photoreceptor cells responsible for color vision.

Figure 45.16 Rods and Cones This scanning electron micrograph of photoreceptors in the retina of a mud puppy (an amphibian) shows cylindrical rods and tapered cones.

ROD CELLS

Rod cells do not produce action potentials, but they release neurotransmitter from their bases, where they form synapses with the next neurons in the visual pathway. Each rod cell has an outer segment, an inner segment, and a synaptic terminal (see **Figure 45.16**). The highly specialized outer segment contains stacks of discs made up of cell membranes densely packed with rhodopsin. These discs capture photons of light. The inner segment contains the cell nucleus, mitochondria, and other organelles. The synaptic terminal is where the rod cell communicates with other neurons.

To see how a rod cell responds to light, we can penetrate a single rod cell with an electrode and record its membrane potential in the dark and in the light, as shown in **Figure 45.17**. From what you have learned about other types of sensory receptors, you might expect that stimulation of the rod cell by light would make its membrane potential less negative, but the opposite is true—it becomes more negative, that is, it becomes hyperpolarized.

Original Paper: Baylor, D. A. and B. J. Nunn. 1986. Electrical properties of the light-sensitive conductance of rods of the salamander *Ambystoma tigrinum*. *Journal of Physiology* 371: 115–145.

The cell membrane of a rod cell hyperpolarizes—becomes more negative—in response to a flash of light. Rod cells do not fire action potentials, but in response to the absorption of light energy, the neuron undergoes a change in membrane potential.

HYPOTHESIS ▶ When a rod cell absorbs photons (light energy), its membrane potential changes in proportion to the strength of the light stimulus.

METHOD

1. Record membrane potentials from the inner segment of a rod cell.
2. Stimulate the rod cells with light flashes of varying intensity and record the results.

RESULTS

CONCLUSION ▶ The membrane potential of rod cells is depolarized in the dark and hyperpolarizes (becomes more negative) in response to light.

Figure 45.17 How Light Stimulates Rod Cells

Rod cell outer segments have cGMP gated sodium channels. In the dark, abundant cGMP in the cell keeps these channels open, creating the dark current. When light is flashed on the dark-adapted rod cell, these Na^+ channels close in proportion to the intensity of the light, and the cell's membrane potential becomes more negative—it hyperpolarizes (see [Figure 45.17](#)). The rate of neurotransmitter release from the base of the cell changes as membrane potential changes. As the rod cell hyperpolarizes, its release of neurotransmitter decreases.

How does the absorption of light by rhodopsin hyperpolarize the rod cell? As illustrated in [Figure 45.15](#), when rhodopsin is excited by light it undergoes conformational changes that initiate a signaling cascade. The dark-adapted rod cell has open Na^+ channels—the depolarizing dark current ([Figure 45.18](#)). Light photons excite rhodopsin, which activates a G protein called transducin. Activated transducin activates a phosphodiesterase (PDE). Activated PDE converts cyclic GMP (cGMP) to GMP, which causes the cGMP gated Na^+ channels to close, changing the balance between the inward flow of Na^+ and the outward flow of K^+ and causing the cell to hyperpolarize.

Figure 45.18 Light Absorption Closes Sodium Channels The absorption of light by rhodopsin initiates a signaling cascade that hyperpolarizes the rod cell.

This cascade may seem like a roundabout way of doing business, but its advantage is its enormous amplification ability. Each molecule of light-excited rhodopsin can activate several

hundred transducin molecules, thus activating a large number of PDE molecules. The catalytic capacity of PDE is great—one PDE molecule can hydrolyze several hundred molecules of cGMP per second. The bottom line is that a single photon of light can result in the closure of a huge number of Na⁺ channels.

CONE CELLS

Cone cells are responsible for the high-acuity color vision of day-active vertebrates such as humans. It is therefore logical that the highest density of cone cells is in the area of the retina that receives light from the center of the visual field, a region called the **fovea** (see [Figure 45.13A](#)). The human fovea has about 160,000 cones per square millimeter. But humans are not the champions of high-acuity vision; a hawk's fovea has almost twice that number of cones, making the hawk's vision much sharper than ours. Birds also have *two* foveae in each eye; one receives light from straight ahead, the other from a more lateral field of vision. The forward-looking foveae make binocular vision possible, while the lateral-looking foveae provide high-acuity vision. Birds use both sets of foveae by frequently turning their heads slightly; they cannot move their eyes in the sockets as humans can.

fovea [L. <i>fovea</i> : a small pit] In the vertebrate retina, the area of most distinct vision.
--

Cones have low sensitivity to light and contribute little to night vision. Night vision depends mostly on rod cells, which is why vision in dim light is mostly in shades of gray and acuity is low. You may have trouble seeing a small object at night when you are looking straight at it—that is, when its image is falling on your fovea. If you look a little to the side, so that the image falls on a rod-rich area of your retina, you see the object better. Astronomers looking for faint objects in the sky learned this trick a long time ago. The retinas of nocturnal animals, such as flying squirrels, contain a high percentage of rods. By contrast, some animals that are active only during the day (such as chipmunks) have mostly cones in their retinas.

The human retina has three kinds of cone cells, each containing slightly different opsin molecules that differ in the wavelengths of light they absorb best. Although the same 11-*cis*-retinal group is the light-absorber in all three kinds of cones, its molecular interactions with opsin determine the spectral sensitivity of the cone cell as a whole ([Figure 45.19](#)). Those that absorb maximally around 419 nanometers (nm) are called S-cones for short wavelength (blue range). Those that absorb maximally around 531 nm are called M-cones for medium wavelength (green range), and those that absorb maximally around 559 nm are called L-cones for long wavelength (yellow-red range). Because different wavelengths of light are differentially absorbed by the different cone cell visual pigments, the brain interprets the relative inputs from the different classes as a full range of color. Color blindness in humans results from the absence or dysfunction of one or more of the three classes of cone cells. Some mammals have only one or two classes of cone cells, whereas birds have four.

Figure 45.19 Absorption Spectra of Cone Cells The three kinds of cone cells contain slightly different visual pigments that absorb different wavelengths of light.

Information flows through layers of neurons in the retina

The human retina is organized into layers of neurons that receive visual information and process it before sending it to the brain (**Figure 45.20**). Closest to the lens (and thus to light input) is a layer of [ganglion cells](#); a central layer contains three neuronal types, [bipolar cells](#), [horizontal cells](#), and [amacrine cells](#); and at the “rear” of the retina lie the photoreceptors (rods and cones). The layers of cells between the photoreceptors and the ganglion cells process information about the visual field.

Figure 45.20 The Human Retina Five layers of neurons receive and process visual information. The rods and cones are photoreceptors. The other four layers are the ganglion cells, the bipolar cells, the horizontal cells, and the amacrine cells, all of which are involved in transmitting light signals received by the photoreceptors to the brain.

Media Clip 45.1 Into the Eye www.Life11e.com/mc45.1

Activity 45.4 Structure of the Human Retina www.Life11e.com/ac45.4

ganglion cells Cells at the front of the human retina that transmit information from the bipolar cells to the brain.

bipolar cells Cells in the retina that communicate between photoreceptors and ganglion cells.

horizontal cells Cells in the retina that communicate laterally between photoreceptors and bipolar cells.

amacrine cells Cells in the retina that communicate laterally between ganglion and bipolar cells.

GANGLION AND BIPOLAR CELLS

From our discussion of rod cells, you know that the photoreceptor cells at the back of the retina hyperpolarize in response to light and do not generate action potentials. The ganglion cells at the front of the retina do, however, fire action potentials. The axons of ganglion cells form the [optic nerves](#) that travel to the brain.

optic nerve The nerve that carries information from the retina of the eye to the brain.

The ganglion cells are connected to the photoreceptors by bipolar cells. Changes in the membrane potential of rods and cones in response to light alter the rates at which the rods and cones release neurotransmitter at their synapses with the bipolar cells. In response to this neurotransmitter, the membrane potentials of the bipolar cells change, altering the rate at which they release neurotransmitter onto ganglion cells. The neurotransmitter release from the bipolar cells determines the rate at which ganglion cells fire action potentials. Thus the direct flow of information in the retina is from photoreceptor to bipolar cell to ganglion cell. The ganglion cells send the information to the brain via the optic nerves.

Each human eye contains about 1.2 million ganglion cells but more than 100 million rods and cones. Therefore there must be convergence of information as it passes from the photoreceptors to the ganglion cells. A given bipolar cell can receive input from multiple rods or multiple cones, but not from both. The relationship between photoreceptors, bipolar cells, and ganglion cells depends on their location on the retina. In the fovea, a ganglion cell may receive input from as few as five photoreceptors, but in the periphery of the retina, a ganglion cell may receive input from thousands of photoreceptors. Visual acuity is a reflection of these quantitative relationships.

The patch of photoreceptors that communicates with a ganglion cell forms a circular receptive field. When light falls on a receptive field, its ganglion cell can be either excited or inhibited. As mentioned above, each ganglion cell sends an axon to the brain in the optic nerves. Thus the information coming from the retina to the brain is about the pattern of patches of light and dark falling on the retina. We'll return to a discussion of how the brain constructs the visual field from the input from receptive fields in [Chapter 46](#).

HORIZONTAL AND AMACRINE CELLS

The other two cell layers, the horizontal cells and the amacrine cells, consist of interneurons that communicate laterally across the retina. Horizontal cells form synapses with neighboring photoreceptors and bipolar cells. Thus light falling on one photoreceptor can influence the sensitivity of its neighbors to light. This lateral flow of information enables the retina to sharpen the perception of contrast between light and dark patterns. Amacrine cells form local interconnections between bipolar cells and ganglion cells. Some amacrine cells are highly sensitive to changing illumination or to motion. Others assist in adjusting the sensitivity of the

eyes according to the overall level of light falling on the retina. When background light levels change, amacrine cell connections to the ganglion cells adjust the range of intensities to which they are sensitive. Thus even with large changes in background illumination such as going from outdoors into a building, the eyes are still sensitive to small, rapid changes in the pattern of light falling on the retina. The light reflected from this page can vary by nine orders of magnitude (1,000,000,000-fold) between a sunny outdoor environment and a moonless night. Even though our eyes function best over a light-intensity range of only two orders of magnitude, modulation by amacrine cells can rapidly shift that functional range to accommodate a wide range of light intensities.

45.4 recap

Vertebrates have image-forming eyes in which a lens focuses incoming light onto the photosensitive retina. Opsin molecules are responsible for light sensitivity in all animals, and in mammals opsins are contained in receptor cells called rods and cones. Slight differences in the opsin molecules result in differences in spectral sensitivity, which is the basis for color vision. Rods and cones do not fire action potentials, but their graded membrane potentials alter neurotransmitter release onto retinal bipolar cells. The bipolar cells in turn influence ganglion cells that do fire action potentials in their axons, which travel in the optic nerves to the brain. Two other types of retinal cells, horizontal and amacrine cells, sharpen contrast and adjust sensitivity of the retina, respectively.

learning outcomes

You should be able to:

- Trace the steps for how a photon of light is transduced into a change in membrane potential.
 - Compare the properties and locations of rod and cone cells in the retina.
 - Describe the structural implications for movement detection and visual acuity.
 - Explain ganglion cell receptive fields in terms of the lateral processing afforded by the horizontal and amacrine cells.
-
1. Explain why a compound eye is better at detecting movement than at forming images.
 2. How do photons of light change the receptor potential of rod cells?
 3. Explain how rods and the various cones differ in their spectral sensitivity.
 4. If you are looking straight ahead and someone holds up a colored card on your right or left side, why can't you tell what the color is?
 5. Give two reasons why your vision is impaired when you come from bright outside light into a dimly lit room.

Knowing the path of information from sensory receptor cells to the CNS still does not tell us how that information is processed by the brain. What does the eye tell the brain, for example, in response to a pattern of light falling on the retina? In [Chapter 46](#) you will learn how the mammalian brain reassembles sensory information into our perception of the world.

QA How do pit vipers "see" in the dark?

The pit organs of rattlesnakes are the infrared detectors that signal the presence of warm-blooded prey. In this chapter we considered how the pit organs transduce infrared radiation into neural information. Infrared is a portion of the electromagnetic radiation spectrum, as is visible light. So could the receptor cells in the pit organs be modified photoreceptors? Or have they evolved from the types of sensory neurons in the skin that sense temperature? The temperature-sensitive neuron theory seems more likely since there is no rhodopsin in the pit organs. But how did such neurons acquire an acute sensitivity to minute changes in temperature of the pit organ caused by distant infrared emitters? The experiments covered in Investigating life: How Do Pit Vipers "See" in the dark? identified a particular TRP channel that is highly expressed in the trigeminal ganglia but not in the dorsal root ganglia of rattlesnakes. These experiments also revealed that the TRPA1 channel is not highly expressed in the TG or DRGs of non-pit snakes, but is highly expressed in a distantly related pit snake, the python. In the online exercise to Investigating life: How Do Pit Vipers "See" in the dark? it was determined that expression of the TRPA1 gene in frog oocytes causes them to have a steep temperature sensitivity in the range of 36 °C to 42 °C. Thus we can conclude that the TRPA1 channel has evolved along with the pit organ to enable pit vipers such as the rattlesnake to detect warmblooded prey.

Future directions

The identification of specific genes that convey specific sensory capabilities—for example, identification of the different opsin genes for color vision and the TRPA1 gene for infrared detection—raise the possibility that genetic engineering efforts could be directed toward expanding the sensory capabilities of animals, and even humans. What would it be like to be able to see in the infrared and the ultraviolet ranges or to hear infrasound and ultrasound? Would the human brain be able to process and integrate that huge amount of additional information? How would our conscious perception of reality be changed?

► 45.1 Sensory Receptor Cells Convert Stimuli into Action Potentials

- Sensory receptor cells, also known as [sensors](#) or [receptors](#), transduce information about an animal's external and internal environment into action potentials that the brain perceives as different forms of sensory information.

sensor Cell that is responsive to a particular type of physical or chemical stimulation.

receptor See receptor protein, sensor.

- [Receptor potentials](#) can spread to regions of the cell membrane that generate action potentials. Some sensors do not fire action potentials but release neurotransmitter onto sensory neurons that do fire action potentials. **Review [Figure 45.1](#)**

receptor potential The change in the resting potential of a sensory cell when it is stimulated.

- Sensors have [receptor proteins](#) that cause ion channels to open or close, affecting the receptor cell's membrane potential. Some receptors open ion channels physically through forces such as pressure or stretch. Other receptors act through signal transduction pathways to generate receptor potentials. A large family of genes called transient receptor potential (TRP) genes is responsible for many modalities of sensory transduction. **Review [Figure 45.2, Investigating Life: How Do Pit Vipers “See” in the Dark?](#)**

receptor protein A protein that can bind to a specific molecule, or detect a specific stimulus, within the cell or in the cell's external environment.

- The interpretation of action potentials as particular sensations depends on which neurons in the central nervous system receive them.
- [Adaptation](#) enables the nervous system to ignore irrelevant or continuous stimuli while remaining responsive to relevant or new stimuli.

adaptation (a dap tay' shun) (1) In evolutionary biology, a particular structure, physiological process, or behavior that makes an organism better able to survive and reproduce. Also, the evolutionary process that leads to the development or persistence of such a trait. (2) In sensory neurophysiology, a sensory cell's loss of sensitivity as a result of repeated stimulation.

► 45.2 Chemoreceptors Respond to Specific Molecules

- [Chemoreceptors](#) are responsible for [olfaction](#), [gustation](#), and the sensing of [pheromones](#).

chemoreceptor A receptor protein that binds to specific molecules (such as odorant molecules or pheromones) in the environment.

olfaction (ole fak' shun) [L. *olfacere*: to smell] The sense of smell.

gustation The sense of taste.

pheromone (feer' o mone) [Gk. *pheros*: carry + *hormon*: excite, arouse] A chemical substance used in communication between organisms of the same species.

- Mammalian **olfactory receptor neurons (ORNs)** project directly to the **olfactory bulb** of the brain. ORNs for the same **odorant** project to the same area of the olfactory bulb.

olfactory receptor neurons (ORNs) Neurons with receptors for different odorants.

olfactory bulb Structure in the vertebrate forebrain that receives and processes input from olfactory receptor neurons.

odorant A molecule that can bind to an olfactory receptor.

- Each ORN expresses one receptor protein that can bind a specific type of molecule or ion. Binding causes a second messenger to open ion channels, which creates an action potential. **Review Figure 45.3**
- Pheromones are chemicals that communicate information among individuals of the same species.
- In vertebrates, **taste buds** in the mouth cavity are responsible for gustation. The five basic tastes are sweet, salty, sour, bitter, and umami. **Review Figure 45.5**

taste bud A structure in the epithelium of the tongue that includes a cluster of chemoreceptors innervated by sensory neurons.

- Photosensitivity in animals depends on the absorption of photons of light by the visual pigment opsin, which contains a light absorbing group called 11-*cis*-retinal. Absorption of light is the first step in a cascade of intracellular events leading to a change in the membrane potential of the photoreceptor cell. **Review Figures 45.15, 45.18, Animation 45.2**
- Vertebrates have two types of photoreceptors, rod cells and cone cells. Rod cells are more sensitive to light and are responsible for dim light vision. cone cells are less sensitive to light but are responsible for high-acuity and color vision.
- Photoreceptors do not fire action potentials. light hyperpolarizes rod cells, and their release of neurotransmitter decreases. **Review Figure 45.17**

► 45.3 Mechanoreceptors Respond to Physical Forces

- The skin contains a variety of **mechanoreceptors** that respond to touch and pressure. The density of mechanoreceptors in any skin area determines the sensitivity of that area. **Review Figure 45.6**

mechanoreceptor A cell that is sensitive to physical movement and generates action potentials in response.

- Stretch receptors in **muscle spindles** and in **Golgi tendon organs** inform the CNS of the positions of and loads on parts of the body. **Review Figure 45.7**

muscle spindles Mechanoreceptors embedded in skeletal muscle that sense changes in the length of the muscle.

Golgi tendon organ A mechanoreceptor found in tendons and ligaments; provides information about the force generated by a contracting muscle.

- **Hair cells** are mechanoreceptors of the auditory and vestibular systems. Physical bending of the hair cells' **stereocilia** alters their receptor proteins and therefore their membrane potentials. **Review Figure 45.8**

hair cell A type of mechanoreceptor in animals. Detects sound waves and other forms of motion in air or water.

stereocilia Fingerlike extensions of hair cell membranes whose bending initiates sound perception. (See hair cell.)

- In mammalian auditory systems, ear pinnae collect and direct sound waves to the **tympanic membrane**, which vibrates in response to sound waves. The movements of the tympanic membrane are amplified through a chain of **ossicles** that conduct the vibrations to the **oval window**. Movements of the oval window create pressure waves in the fluid-filled **cochlea**. **Review Focus: Key Figure 45.9 Activity 45.**

tympanic membrane [Gk. *tympanum*: drum] The eardrum.

ossicles Three bones in the middle ear that transmit vibrations from tympanum to the oval window of the inner ear. Individually named the malleus ("hammer"), incus ("anvil"), and stapes ("stirrup").

oval window The flexible membrane that, when moved by the bones of the middle ear, produces pressure waves in the inner ear.

cochlea (kock' lee uh) [Gk. *kokhlos*: snail] A spiral tube in the inner ear of vertebrates; it contains the sensory cells involved in hearing.

- The basilar membrane running down the center of the cochlea is distorted by pressure waves at specific locations that depend on the frequency of the wave. These distortions cause hair cells in the **organ of Corti** to bend and to release neurotransmitter, generating action potentials in the cochlear nerve that are transmitted to the auditory cortex of the brain. **Review Figure 45.10, Animation 45.**

organ of Corti Structure in the inner ear that transforms mechanical forces produced from pressure waves ("sound waves") into action potentials that are sensed as sound.

- Hair cells are also the mechanoreceptors of the organs of equilibrium in the mammalian vestibular system, which include the semicircular canals and the saccule and utricle. **Review Figure 45.11, Activity 45.2**

► 45.4 Photoreceptors Respond to Light

- Visual systems range from the simple **eye cups** of flatworms, which sense the direction of a light source, to the **compound eyes** of arthropods, which detect shapes and patterns, to the image-forming eyes of vertebrates and cephalopods. **Review Figures 45.12, 45.13**

eye cups Photosensory organs in flatworms; components of one of the simplest visual systems in animals.

- Vertebrate and cephalopod eyes focus detailed images of the visual field onto dense arrays of photoreceptors that transduce the visual image into neural signals.**Review** [Figures 45.13](#), [45.14](#), [Activity 45.3](#)
- Rhodopsin is the visual pigment of rod cells. The visual pigments of cone cells have three different opsin components, which gives them different spectral sensitivities.**Review** [Figure 45.19](#)
- The vertebrate retina consists of layers of neurons lining the back of the eye. The light-absorbing photoreceptor cells are at the rear of the retina. The axons of the ganglion cells are bundled together in the optic nerves. Between the photoreceptors and the ganglion cells are neurons that process information from the photoreceptors.**Review** [Figure 45.20](#), [Activity 45.4](#)

Review

5.3 The ear converts sound waves in air to pressure waves in fluid that bend hair cells to create auditory sensation.

Original Paper: Corcoran, A. J. and W. E. Conner. 2012. Sonar jamming in the field: Effectiveness and behavior of a unique prey defense. *Journal of Experimental Biology* 215: 4278-4287.

Bats prey on nocturnal moths using echolocation. A bat pursuing prey emits ultrasonic signals that reflect off flying moths and echo back to the bat, enabling it to home in on the prey. Moths can “hear” ultrasonic bat signals through paired auditory organs (tympana) that respond to both low- and high-intensity sound waves. The moths have evolved evasive behaviors to evade capture.

Some moths use rapid changes in flight behavior, such as turning away or rapid dives, to evade capture. Others use unique tymbal organs, located in the thorax, to produce ultrasonic clicks. Researchers hypothesized that these clicks serve as echolocation-jamming mechanisms. To test this hypothesis they used tiger moths (*Bertholdia trigona*). One group of moths ($N = 41$) had their tymbal organs punctured, making them incapable of producing sounds (silenced), and another group ($N = 38$) were left with intact tymbal organs (clicking). Both groups were released into bat feeding areas. The fates of the released moths were documented with video and audio recordings. Results of the experiment are shown in the figures.

In [Figure A](#), numbers over the bars show the number of attacks when silenced or clicking moths exhibited a particular evasive behavior. Statistically, there was no difference between behaviors or between silenced moths and clicking moths.

In [Figure B](#), numbers over the bars represent the number of captures that were made when silenced or clicking moths exhibited a particular evasive behavior. In all three categories the difference between silenced moths and clicking moths was statistically significant.

Questions

1. According to the data in Figure A, were moths with disrupted tymbal organs still capable of responding to the bats with evasive behaviors? Explain your answer. Why is this important for the validity of this experiment?
2. According to the data in Figure B, what effect did disruption of the tymbal organs have on the number of captures? How do these results support the hypothesis that the tymbal organ in *B. trigona* provides an echolocation-jamming function?
3. The sound pulses produced by the bats (*Myotis* sp.) for echolocation in this study have a frequency of around 50 KHz (50,000 cycles per second). The echo from the moth has the same frequency. The upper limit of human hearing is 20,000 Hz. How do you think the basilar membrane in the bat's cochlea differs in structure from the human basilar membrane?

The Mammalian Nervous System: Structure and Higher Functions

The extraordinary ability of taxicab drivers in London to navigate its maze of streets and byways prompted a study that revealed London cabbies to have larger than normal posterior hippocampi — a brain region implicated in the memory of spatial relationships in the environment.

[16.1 Functions Are Localized in the Nervous System](#)

[16.2 Nervous System Functions Rely on Neural Circuits](#)

[16.3 Higher Brain Functions Involve Integration of Multiple Systems](#)

The Brains of Taxi Drivers

Compare Google maps of London and New York City at the same scale. In which city do you think it is easier to drive a taxi? Eleanor Maguire at University College London was so impressed with the navigational abilities of London taxi drivers that she investigated whether there was anything “special” about their brains. Using magnetic resonance imaging, Maguire and her colleagues examined the brains of taxi drivers with varying numbers of years of experience and compared them with each other and with the brains of control subjects who were not taxi drivers. The studies revealed significant differences in the sizes of a brain region called the hippocampus.

The hippocampus is involved in learning and memory. The posterior hippocampus in particular is implicated in the memory of spatial relationships among objects in the environment. Maguire found that the posterior hippocampi of taxi drivers were larger than those of control subjects and that, among the cab drivers themselves, there was a positive correlation between the size of the posterior hippocampus and years of driving experience.

In Matt Wilson’s lab at the Massachusetts Institute of Technology, researchers record the activity of hippocampal neurons of rats running in a maze. Specific neurons called “place cells” fire action potentials only when the rat is at a particular location in the maze. Thus when the rat runs the maze from beginning to end, a sequence of cell firing is recorded. Sometimes when the rat is resting, the same sequence is recorded but is speeded up about 20 times, or the reverse sequence is recorded. It seems as if the recordings are reflecting what the resting rat is thinking—where it has been, where it is going to go. In a maze with a choice point (go right or go left), the sequence recorded when the rat is resting at the start position frequently predicts which direction it will turn.

The hippocampus is important for acquiring memories and consolidating them into long-term memory. We also know that sleep is important for learning. Could something be happening in the hippocampus during sleep to promote memory?

Can recordings of place cells reveal processes of memory consolidation during sleep?

46.1 Functions Are Localized in the Nervous System

The organization of the mammalian nervous system can be described anatomically and functionally. In anatomical terms, all vertebrate nervous systems consist of three parts: a brain, a spinal cord, and a set of peripheral nerves that reach all parts of the body. As discussed in [Key Concept 44.4](#), the brain and spinal cord are the **central nervous system**, or **CNS**, and the neurons that connect the CNS to all the tissues and sensors of the body are the **peripheral nervous system**, or **PNS**. An additional division of the nervous system exists in the gut; we will discuss this **enteric nervous system** in [Chapter 50](#).

central nervous system (CNS) That portion of the nervous system that is the site of most information processing, storage, and retrieval; in vertebrates, the brain and spinal cord. (Contrast with peripheral nervous system.)

peripheral nervous system (PNS) The portion of the nervous system that transmits information to and from the central nervous system, consisting of neurons that extend or reside outside the brain or spinal cord and their supporting cells. (Contrast with central nervous system.)

enteric nervous system The nerve nets in the submucosa and between the smooth muscle layers of the vertebrate gut.

focus your learning

Conscious sensory and unconscious physiological information flow to the central nervous system via afferent neurons, resulting in efferent outputs to voluntary muscles (i.e., movement) and in involuntary commands over autonomic responses.

From anterior to posterior, the embryonic neural tube gives rise to the cerebrum, thalamus/hypothalamus, midbrain structures, and cerebellum/pons/medulla, respectively.

Specific areas within the five lobes of the cerebral cortex have sensory, motor, and associative functions.

Humans are called the “big-brain primates,” but factors other than size contribute to brain function in humans.

Recall from [Key Concept 45.1](#) that a neuron is an electrically excitable cell that communicates via an axon. When used in the context of a nervous system, the term **nerve** refers to a bundle of axons in the PNS that carry information about many things simultaneously. Some axons in a nerve may be carrying information to the CNS while other axons in the same nerve are carrying information from the CNS to the body's organs. A discussion of the functional organization of the nervous system refers to these paths of information flow. In this chapter we will divide the anatomy of the mammalian brain, spinal cord, and PNS into smaller, discrete functional units.

nerve A structure consisting of many neuronal axons and connective tissue.

Functional organization is based on flow and type of information

Figure 46.1 illustrates the major avenues of information flow through the human nervous system. The white boxes explain the four divisions of the PNS; two of these bring information from the periphery to the CNS, and two transmit information from the CNS to the periphery.

Figure 46.1 Organization of the Nervous System The peripheral nervous system carries information to (afferent) and from (efferent) the central nervous system (center circle in the diagram). The CNS also receives hormonal inputs and produces hormonal outputs (see [Key Concept 40.2](#)).

Q: How do hormonal inputs reach the CNS and hormonal outputs leave the CNS?

- The **afferent** portion of the PNS ([Figure 46.1](#), left) carries information from sensory receptor cells to the CNS. We are *conscious* of much of this information (e.g., light, sound, skin temperature, limb position), but we are usually *unconscious* of the information involved in physiological regulation (e.g., blood pressure, deep body temperature, blood oxygen levels).

afferent (af' ur unt) [L. *ad*: toward + *ferre*: to carry] Carrying to, as in neurons that carry impulses to the central nervous system (**afferent neurons**), or a blood vessel that carries blood to a structure (**afferent arterioles**). (Contrast with efferent.)

- The **efferent** portion of the PNS ([Figure 46.1](#), right) carries information from the CNS to the muscles and glands of the body. Efferent pathways are divided into a *voluntary* division that executes our conscious movements; and an *involuntary*, or *autonomic*, division that controls physiological functions.

efferent (ef' ur unt) [L. ex: out + *ferre*: to bear] Carrying outward or away from, as in neurons that carry impulses outward from the central to the peripheral nervous system (**efferent neurons**), or a blood vessel that carries blood away from a structure (**efferent arterioles**). (Contrast with afferent.)

In addition to the neural information it receives from the PNS, the CNS receives chemical information from hormones circulating in the blood. In turn, neurohormones released by neurons enter the circulation and affect neurons and other cells distant from the site of release (see [Key Concept 40.1](#)).

The anatomical organization of the CNS emerges during development

Early in the development of a vertebrate embryo, a tube of neural tissue forms (see [Key Concept 43.4](#)). At its anterior end, this neural tube forms three swellings that become the [hindbrain](#), [midbrain](#), and [forebrain](#). The rest of the neural tube becomes the spinal cord. Peripheral nerves sprout from the midbrain and hindbrain (the cranial nerves) and from the spinal cord (the spinal nerves). From these early stages we see the linear axis of information flow in the nervous system. Although the developing brain will fold and become a complex structure, the information flow in the adult nervous system will follow paths that emerge from the simple, linear neural tube.

hindbrain The region of the developing vertebrate brain that gives rise to the medulla, pons, and cerebellum. (Compare with forebrain, midbrain.)

midbrain One of the three regions of the vertebrate brain. Part of the brainstem, it serves as a relay station for sensory signals sent to the cerebral hemispheres. (Compare with forebrain, hindbrain.)

forebrain The region of the vertebrate brain that comprises the cerebrum, thalamus, and hypothalamus. (Compare with hindbrain, midbrain.)

Each of these three regions of the embryonic brain develops into several structures in the adult brain ([Figure 46.2](#)). From the embryonic midbrain come structures that integrate information from the different senses and coordinate motor responses. From the hindbrain come the [medulla](#), the [pons](#), and the [cerebellum](#). The medulla is continuous with the spinal cord, the pons is anterior to the medulla, and the cerebellum is a dorsal outgrowth of the pons. The medulla and pons contain distinct groups of neurons involved in controlling physiological functions such as breathing, circulation, and basic motor patterns such as swallowing and vomiting. All information traveling between the spinal cord and higher brain areas must pass through the pons, the medulla, and the midbrain, which are collectively known as the [brainstem](#).

30 days

The brain develops from the anterior embryonic neural tube.

60 days

Forebrain

The forebrain develops into two major divisions, the **telencephalon** and **diencephalon**.

180 days

The telencephalon develops into the cerebrum.

The hindbrain develops into three major divisions: the cerebellum, pons, and medulla.

Adult brain (midsagittal section, right cerebral hemisphere)

The diencephalon develops into the **thalamus** and **hypothalamus**.

Figure 46.2 Development of the Central Nervous System In vertebrate embryos, the anterior end of the hollow neural tube differentiates into forebrain, midbrain, and hindbrain. Each of these regions develops into several structures of the adult brain. The remainder of the neural tube becomes the spinal cord.

medulla (meh dull' luh) (1) The inner, core region of an organ, as in the adrenal medulla (adrenal gland) or the renal medulla (kidneys). (2) The portion of the brainstem that connects to the spinal cord.

pons [L. *pons*: bridge] Region of the brainstem anterior to the medulla.

cerebellum (sair uh bell' um) [L. diminutive of *cerebrum*: brain] The brain region that controls muscular coordination; located at the anterior end of the hindbrain.

brainstem The portion of the vertebrate brain between the spinal cord and the forebrain, made up of the medulla, pons, and midbrain.

One function of the cerebellum is coordinating muscle activity and maintaining balance. It is like the director of a movie; the cerebellum receives a “script” of the commands going to the muscles from higher brain areas, and it receives information about the actual performance coming up the spinal cord from the “actors”—the joints and muscles. The cerebellum compares the “script” with the performance and refines motor commands accordingly. Damage to the cerebellum results in loss of fine motor control and coordination.

The embryonic forebrain develops a central region called the **diencephalon** and a surrounding structure called the **telencephalon**. The diencephalon is the core of the forebrain and consists of an upper structure, the **thalamus**, and a lower structure, the **hypothalamus**. The thalamus is the final relay station for sensory information going to the telencephalon. The hypothalamus receives a lot of physiological information of which we are not conscious, and it uses that information to regulate many physiological functions and biological drives. A major function of the hypothalamus is to control the pituitary gland (see [Key Concept 40.2](#)).

diencephalon The portion of the vertebrate forebrain that develops into the thalamus and hypothalamus.

telencephalon The outer, surrounding structure of the embryonic vertebrate forebrain, which develops into the cerebrum.

thalamus [Gk. *thamos*: chamber] A region of the vertebrate forebrain; involved in integration of sensory input.

hypothalamus The part of the brain lying below the thalamus; it coordinates water balance, reproduction, temperature regulation, and metabolism.

The embryonic telencephalon gives rise to the **cerebrum**, consisting of the left and right **cerebral hemispheres**. The outer layer of the cerebrum is the **cerebral cortex**, a thin layer rich in cell bodies. If we compare vertebrate groups from fish through amphibians, reptiles, and mammals, the cerebrum increases in size, complexity, and importance—an evolutionary trend called telencephalization (see [Figure 44.15](#)). In humans, the cerebrum is by far the largest part of the brain and plays major roles in sensory perception, learning, memory, and conscious behavior.

cerebrum (su ree' brum) [L. brain] The dorsal anterior portion of the forebrain, making up

the largest part of the brain of mammals; the chief coordination center of the nervous system and the major information-processing areas of the vertebrate brain consists of two cerebral hemispheres.

cerebral hemispheres The bilateral divisions of the cerebrum.

cerebral cortex The thin layer of gray matter (neuronal cell bodies) that overlies the cerebrum.

The spinal cord transmits and processes information

The spinal cord conveys information to and from the brain. However, the spinal cord is more than an information pipe. As you saw in [Key Concept 44.4](#), the spinal cord carries out integrative functions as well. The knee-jerk reflex (see [Figure 44.14](#)) is an example of a circuit between the PNS and the spinal cord that controls a simple behavioral function. That simple circuit can be built on to control more complex behaviors such as the withdrawal reflex, which involves readjusting tension in many muscles on both sides of the body to coordinate movement and maintain balance.

The brainstem carries out many autonomic functions

Swallowing, salivating, breathing, eye movements, blood pressure regulation, and gut activity are only a few of the many autonomic functions that are localized in the medulla, the pons, and the midbrain. To carry out these functions, the brainstem has its own components of the PNS, the 12 paired [cranial nerves](#). You encountered the olfactory nerve, the optic nerve, and the auditory nerve (cranial nerves I, II, and VIII) in [Chapter 45](#). Another one, cranial nerve X, is called the vagus (“wandering”) nerve because it travels into the body cavity and communicates with many of the organs, including the heart and the gut. You will encounter the vagus nerve in subsequent chapters.

cranial nerves The 12 pairs of nerves that go directly from the brain to different parts of the body without going down the spinal cord.

Anatomically distinct groups of neurons in the CNS that work together as a unit are called a [nucleus](#) (not to be confused with the nucleus of a single cell). Axons from the neurons of many brainstem nuclei extend to various regions of the brain and modulate brain activity; for example, brainstem nuclei are involved in keeping the higher brain areas awake or allowing them to sleep. All of the sensory information coming up the neural axis from the spinal cord passes through the brainstem on its way to the forebrain, and many of these ascending neuronal tracts give off branches to the awake-promoting nuclei in the brainstem. Because the neuronal circuitry in this part of the brain is so complicated and because activity in these ascending sensory pathways can promote wakefulness, the core of the brainstem has been termed the [reticular-activating system](#) (“reticular” means netlike). Damage to the brain or spinal cord below the reticular-activating system can result in paralysis but leave sleep-wake cycle behavior normal. Damage above the level of the reticular-activating system can interrupt ascending wake-promoting activity resulting in a coma.

nucleus (new’ klee us) [L. *nux*: kernel or nut] (1) In cells, the centrally located compartment of eukaryotic cells that is bounded by a double membrane and contains the chromosomes. (2) In the brain, an identifiable group of neurons that share common characteristics or functions.

reticular-activating system [L. *reticulum*: net] A central region of the vertebrate brainstem that includes complex fiber tracts conveying neural signals between the forebrain and the spinal cord, with collateral fibers to a variety of nuclei that are involved in autonomic functions, including arousal from sleep.

The core of the forebrain controls physiological drives, instincts, and emotions

As mentioned above, the diencephalon consists of the thalamus and the hypothalamus. The thalamus communicates sensory information to the cerebral cortex; the hypothalamus receives information about physiological conditions in the body and regulates many homeostatic functions. [Key Concept 39.5](#) describes how the hypothalamus is involved in regulating body temperature, and [Key Concept 40.3](#) discusses the intimate association between the hypothalamus and the pituitary gland in the control of many homeostatic functions.

The forebrain of all vertebrates includes a phylogenetically old, complex set of structures called the **limbic system** (**Figure 46.3**). The limbic system is responsible for some basic instincts and drives such as hunger and thirst, sexual behavior, and emotions. Within the limbic system there are areas that, when stimulated with small electric currents, can cause intense sensations of pleasure, pain, or rage.

limbic system A group of evolutionarily primitive structures in the vertebrate telencephalon that are involved in emotions, drives, instinctive behaviors, learning, and memory.

Figure 46.3 The Limbic System The evolutionarily primitive parts of the forebrain are referred to as the limbic system. The hippocampus is involved in forming long-term memory. The amygdala triggers fear emotions and fear memories.

Pleasure and pain centers in the limbic system are believed to play roles in learning and in physiological drives. One component of the limbic system—the **amygdala**—is involved in fear and fear memory. If a certain portion of the amygdala is damaged or chemically blocked, an animal that becomes tame and cannot learn to be afraid of a situation that would normally induce a strong fear reaction. The amygdala is involved in post-traumatic stress disorder (PTSD). Another part of the limbic system, the **hippocampus**, is involved in the transfer of certain types of short-term memory to long-term memory, as discussed in the chapter opener and in [**Investigating Life: Place Cells Reveal Processes of Memory Consolidation during Sleep.**](#)

amygdala A component of the limbic system that is involved in fear and the memory of fearful experiences.

hippocampus [Gk. sea horse] A part of the forebrain that takes part in long-term memory formation.

The cerebrum is responsible for complex behavior and consciousness

The cerebrum is the dominant structure in the mammalian brain. In humans it is so large that it covers all other parts of the brain except the cerebellum (**Figure 46.4A**). Layers of cells at the surface of the cerebrum form the cerebral cortex, which is about 4 millimeters thick and is folded into ridges (**gyri**; singular *gyrus*) and valleys (**sulci**; singular *sulcus*). If the cortex were flattened out, it would be about 1 square meter, but the foldings, or **convolutions**, enable that extensive surface area of cortex to fit within the skull.

Figure 46.4 The Human Cerebrum (A) Each cerebral hemisphere is divided into frontal, temporal, parietal, occipital, and insular lobes. (B) Different functions are localized in particular areas of the four cerebral lobes.

Activity 46.1 The Human Cerebrum www.Life11e.com/ac46.1

gyri (singular: gyrus) The ridges (folds) in the cerebral cortex.

sulci (singular: sulcus) The valleys between the folds of the cerebral cortex.

convolutions Foldings of the vertebrate brain's cerebral cortex into ridges called gyri and valleys called sulci. The level of cortical convolution increases taxonomically and is especially extensive in humans.

As we explore the infoldings of the cerebral cortex and other parts of the brain, we will occasionally mention an individual whose brain was damaged by an accident or other unfortunate event. Until recently the study of such individuals has been the main source of functional information about the human brain, but new imaging technologies such as positron emission tomography (PET) and magnetic resonance imaging (MRI) are providing a wealth of new information and opportunities to study the human brain.

A curious feature of the human nervous system is that the left side of the body is served (in both sensory and motor aspects) mostly by the right side of the brain, and the right side of the body is served mostly by the left side of the brain. Thus sensory input from the right hand goes to the left cerebral hemisphere, and sensory input from the left hand goes to the right cerebral hemisphere. The exception is the head, where the left side is controlled by the left cerebral hemisphere and the right side by the right cerebral hemisphere. The two hemispheres are not symmetrical with respect to all functions. Language abilities, for example, reside predominantly in the left hemisphere in most people.

Different regions of the cerebral cortex have specific functions ([Figure 46.4B](#)). Some of those functions are easily defined, such as receiving and processing sensory information or generating motor commands, but in most humans most of the cortex is involved in higher-order information processing that is less easy to define. These latter areas are given the general name of [association cortex](#), so named because they integrate, or *associate*, information from different sensory modalities and from memory.

association cortex In the vertebrate brain, the portion of the cortex involved in higher-order information processing, so named because it integrates, or associates, information from different sensory modalities and from memory.

To understand the cerebral cortex, it helps to have an anatomical road map. Viewed from the left side, the left cerebral hemisphere looks like a boxing glove for the right hand with the fingers pointing forward, the thumb pointing out, and the wrist at the rear. The “thumb” area is the [temporal lobe](#), the fingers the [frontal lobe](#), the back of the hand the [parietal lobe](#), and the wrist the [occipital lobe](#) (see [Figure 46.4A](#)). What you can’t see from the external view is the [insular cortex](#), which is folded in between the thumb and finger areas of the boxing glove (between the frontal/parietal and the temporal lobes). The right cerebral hemisphere shows a mirror image of this arrangement. We will look at each lobe separately.

temporal lobe One of the four lobes of the cerebral hemisphere; receives and processes auditory and visual information; involved in recognizing, identifying, and naming objects.

frontal lobe The largest of the brain lobes in humans; involved with feeling and planning functions; includes the primary motor cortex.

parietal lobe One of four lobes of the cerebral hemisphere; processes complex stimuli and includes the primary somatosensory cortex.

occipital lobe One of the four lobes of the brain’s cerebral hemisphere; processes visual information.

insular cortex The outer layers of the insular lobe.

Place Cells Reveal Processes of Memory Consolidation during Sleep

Original Paper: Lee, A. K. and M. A. Wilson. 2002. Memory of sequential experience in the hippocampus during slow wave sleep. *Neuron* 36: 1183–1194.

Multiple hippocampal cells were recorded while a rat ran a maze. Individual cells fired only when the rat was at particular locations in the maze; thus the rat's progress through the maze can be represented by a specific sequence of firing of these "place cells." Since memory is consolidated during sleep, are the sequences of place cells expressed during the maze-running experience replayed and processed into long-term memory during sleep?

HYPOTHESIS ▶ Memory of the maze-running experience is represented by a sequence of firing of hippocampal place cells. This sequence is repeated during sleep as part of the process of memory consolidation.

METHOD

1. Record from multiple hippocampal neurons while a rat is running through a maze.
2. Identify sequences of cell firing that reoccur whenever the rat runs the maze.
3. Continue to record the neuronal activity during sleep and determine if similar sequences are occurring with a probability greater than expected from random activity in that group of cells.

CONCLUSIONS

1. Sequences of hippocampal-cell firing that correspond to locations in the maze were highly repeatable and probably represent the coding of that place information in the hippocampus.
2. During sleep, bursts of cell firing sometimes occurred that correspond wholly or partially to the sequences recorded when the rat was running in the maze.

investigating **life work with the data** follows on next page.

RESULTS

- 1 After 30 runs through the maze, a group of nine place cells are identified that fire in the same order correlating with position in the maze.

- 2 The peak firing rate of each neuron can be calculated as a function of position in the maze. When the neurons are arranged in the temporal order of their peak firing rates, you can think of each neuron as being a "letter" in a "word" that codes spatial information about the maze.

- 3 Subsequent recordings while the animal is awake, at rest, or asleep are analyzed for the occurrence of the same or similar "words"—complete or partial sequences of place-cell activity in the same order as the base sequence. Thus a similar word to a nine-letter (nine-neuronal) sequence might be a sequence of seven cells firing in the same order as in the original nine-letter sequence.

work with the data

To conclude that a particular sequence of cell firing observed during sleep is a significant event—meaning that it could be a replay of the waking experience—we have to compare it with the probability that it would occur by random chance. And we need to consider whether an observed sequence that includes some but not all of the components of the baseline “word” is nevertheless a significant event.

What is the minimum number of elements that would have to match the baseline sequence for it to be considered a significant event with $P < 0.01$? To find out, we need to calculate the probabilities of the recorded neurons firing randomly and creating the sequence matches. First, let's consider the probability of a recurrence by chance of the exact nine-“letter” baseline sequence being recorded in a single burst of that group of nine cells. The total number of possible combinations of those nine letters can be calculated as the factorial 9!:

$$9! = 9 \times 8 \times 7 \times 6 \times 5 \times 4 \times 3 \times 2 \times 1 = 362,880$$

In other words, the probability of repeating the entire nine-letter sequence would be 1 out of 362,880. That repeat would have an extremely low probability of occurring and would therefore be a highly significant event. But what if the recorded sequence has only six of the nine cells firing in the proper order? How do you determine the

probability of that? First, calculate the probability of a combination of six cells out of the nine. So for the first cell you have nine choices, for the second you have eight choices, and so forth. Then you have to calculate the probability of that combination of six cells being in the proper sequence, and that will be 1 out of the total number of possible arrangements of those six cells, or 6!. Then what do you do for probabilities of successive events? You multiply the probabilities. For example, if you flip a coin, the probability of heads is 0.5. If you flip it twice, the probability of getting heads both times is 0.5×0.5 , or 0.25.

QUESTIONS▶

1. What is the probability of the sequence 1, 4, 6, 7, 8, 9 out of a random firing of nine cells?
2. What is the probability of a sequence of four letters occurring out of a random firing of nine cells?
3. Are both of the recordings from Questions 1 and 2 low-probability events?
4. What do you note about the time frame of the sequence during sleep versus during wakefulness?

A similar **work with the data** exercise may be assigned in **LaunchPad**.

THE TEMPORAL LOBE

The upper region of the temporal lobe receives and processes auditory information. The association areas of this lobe are involved in recognizing, identifying, and naming objects. Damage to the temporal lobe results in disorders called agnosias, in which the individual is aware of an object but cannot identify it.

Damage to a specific region of the temporal lobe results in the inability to recognize faces. Even old acquaintances cannot be identified by facial features, although they may be identified by other attributes such as voice, body features, and posture. Damage to other association areas of the temporal lobe can cause deficits in understanding spoken language, although speaking, reading, and writing abilities may be intact.

THE FRONTAL LOBE

The frontal and parietal lobes are separated by a deep valley called the central sulcus. A strip of the frontal lobe cortex just in front of the central sulcus is called the **primary motor cortex** (see [Figure 46.4](#)). The neurons in this region control muscles in specific parts of the body; the parts of the body map onto the primary motor cortex, with the head represented in the lower outside region and the legs and feet in the top region near the midline. The graphic drawing of body parts overlying the diagram of the cortex is called a homunculus, and its distortion represents disproportionate innervation. Parts of the body with fine motor control, such as the face and hands, have disproportionate representation ([Figure 46.5A](#)). Electrical stimulation of neurons in different regions of the primary motor cortex causes specific muscles of the body to twitch. Just anterior to the primary motor cortex is the **pre-motor cortex**, which is involved in planning more complex and coordinated movements.

primary motor cortex See motor cortex.

pre-motor cortex The region of the frontal lobe of the cerebrum that is anterior to the primary motor cortex.

Figure 46.5 The Body Is Represented in Primary Motor and Primary Somatosensory Cortexes Neurons in the primary motor cortex (A) control muscles in specific parts of the body, while neurons in the primary somatosensory cortex (B) receive information from specific parts of the body. The locations of these neurons within each cortex correspond to “maps” on which regions of the body are represented in proportion to the amount of innervation they receive.

The association functions of the frontal lobe are diverse and best described as having to do with feeling and planning. They are said to have [executive function](#) and they contribute significantly to personality. People with frontal lobe damage have drastic alterations of personality and difficulty planning future events. A dramatic case of frontal lobe damage is that of Phineas Gage, who in 1848 was an industrious and responsible young railroad construction foreman. Then a blasting accident shot a meter-long, 3-centimeter-wide iron tamping rod through his brain. The rod entered Gage’s head below his left eye, passed through his frontal lobe, and exited the top of his head ([Figure 46.6](#)).

executive functions Cognitive processes (e.g., attentional control, inhibitory control, reasoning, problem solving, planning) that allow goal-directed control of thought and behavior.

Figure 46.6 A Mind-Altering Experience Phineas Gage miraculously survived a nineteenth-century railroad construction accident that blew an iron rod through his brain. His personality, however, was permanently altered from that of a responsible foreman to a sometimes quarrelsome drifter.

Remarkably, Gage survived, but he had a different personality. In the years following his recovery, he was quarrelsome, impatient, obstinate, and used profane language, which he did not do before. He lost his railroad job and earned money by telling his story and exhibiting his scars (and the tamping iron). Several years later, however, he took a job as a stage coach driver in Chile—a challenging job indicating considerable behavioral recovery. He died of a seizure in 1860, at the age of 38. If you are in Boston, you can pay him a visit—his skull, death mask, and the tamping iron are on display in the Warren Anatomical Museum of Harvard Medical School.

THE PARIETAL LOBE

The strip of parietal lobe cortex just behind the central sulcus is the [primary somatosensory cortex](#) (see [Figure 46.4B](#)). This area receives touch and pressure information relayed from the body through the thalamus.

primary somatosensory cortex See somatosensory cortex.

As with the primary motor cortex, the entire body surface can be mapped onto the primary somatosensory cortex ([Figure 46.5B](#)). Areas of the body that have a high density of tactile mechanoreceptors and are capable of making fine discriminations in touch (such as the lips and fingers) have disproportionately large representation. If a very small area of the primary somatosensory cortex is stimulated electrically, the subject reports feeling specific sensations, such as touch, in a localized part of the body.

A major association function of the parietal lobe is attending to complex stimuli. Damage to the right parietal lobe causes a condition called contralateral neglect syndrome, in which the individual tends to ignore stimuli from the left side of the body or the left visual field. Such individuals have difficulty performing complex tasks, such as dressing the left side of the body; an afflicted man may not be able to shave the left side of his face. When asked to copy simple drawings, a person who exhibits this syndrome can do well with the right side of the drawing but not the left.

The parietal cortex is not symmetrical with respect to its role in attention. Damage to the left parietal cortex does not cause the same degree of neglect of the right side of the body. You will see similar asymmetries in cortical function later in the chapter when we discuss language.

THE OCCIPITAL LOBE

The occipital lobe receives and processes visual information. The association areas of the occipital cortex are essential for making sense of the visual world and translating visual experience into language. Some deficits resulting from damage to these areas are specific. In one case, a woman with limited damage was unable to see motion. Her vision was intact, but she could see a waterfall only as a still image, and an approaching car only as a series of a stationary object at different distances.

THE INSULAR CORTEX

The insular cortex, buried deep in the forebrain, receives a great variety of afferent information. The posterior regions receive somatosensory information (e.g., touch, pain, temperature); the middle region combines that with autonomic regulatory information and drives (e.g., hunger, thirst, sex); and the anterior region, which is well developed in higher primates, elephants, and marine mammals, receives information about social interactions. Thus in mammals the insular cortex appears to integrate physiological information from all over the body to create a sensation of how the body “feels,” and in the higher mammals it may extend that function into a sense of self.

The size of the human brain is off the curve

Humans are sometimes called “big-brain primates,” and that is an accurate characterization. Across vertebrate species there is a correlation between body size and brain size ([Figure 46.7](#)). Higher primates such as chimpanzees, baboons, and gorillas all fall above this regression line, but humans stand out because they are so far above the regression line. Gorillas are much larger than humans, but they have smaller brains. Elephants and whales have large brains, but they fall closer to the regression line. Dolphins and humans stand out as having much larger brains than would be predicted by their body sizes.

Figure 46.7 Evolution of the Human Brain Brain size scales to body size across a wide range of vertebrates. The higher primates have larger brains than predicted by the correlation, and humans stand outside this relationship with much bigger brains.

The increase in brain size in humans is mostly due to an increase in the cerebral cortex. The human brain is also highly convoluted, and more of it is devoted to associative functions.

The correlation of brain size to body size does not tell the whole story of human brain evolution, however. In **Figure 44.15**, which compares the brains of four vertebrates, we see that the forebrain is larger than other brain regions, and in mammals this is seen as an elaboration of the cerebral cortex. If we look just at mammals, another feature is the degree of convolution of the cortex. Since the cortex is a layered, two-dimensional array of neurons, the area of cortex is increased by convolutions, which are greatest in humans. And finally, the percent of the cortex that is association cortex (i.e., devoted to the integration of information) is by far the greatest in humans. It is these evolutionary changes, primarily in the cortex, that provide the resources for the intellectual capacity of humans—a topic to which we will return at the end of the chapter.

46.1 recap

The central nervous system communicates with the rest of the body through the peripheral nervous system. We are conscious of some sensory information coming into the CNS, but we are not conscious of other afferent information used in physiological regulation. The brain develops from the anterior region of the embryonic neural tube. The fore-brain gives rise to the cerebrum, which is divided into five lobes. Specific functions such as somatosensation, vision, hearing, motor control, smell, and speech are localized in specific cortical areas. At the center of the cerebrum is the limbic system which contributes to the processing of emotions, inborn responses, and some types of memory. Underneath the cerebrum is the hypothalamus, responsible for many autonomic functions, and the thalamus, which directs ascending information to the cortex. The midbrain and hindbrain constitute the brainstem, within which are located many nuclei that support autonomic functions, including sleep and wakefulness. Evolution of the human brain has resulted in a greatly increased cerebral cortex devoted to integration of information.

learning outcomes

You should be able to:

- Describe and classify the types of afferent information to and efferent information from the nervous system.
- Describe the developmental relationships between the major brain regions, starting with the forebrain, midbrain, and hindbrain and ending with structures such as the amygdala, hypothalamus, primary motor cortex, reticular-activating system, and other components of the adult brain.
- Sketch the five lobes of the cerebrum and identify the primary sensory and motor areas.
- Characterize the human brain in comparison to other mammals.

1. Given your understanding of afferent and efferent systems operating in the nervous system, give examples of brain-body feedback loops that influence each of the following:
 - a. Voluntary behavior through a conscious sensory stimulus
 - b. Involuntary responses through a conscious sensory stimulus
 - c. Involuntary responses through an unconscious stimulus

2. In the developmental and lethal disorder anencephaly, the anterior-most region of the developing neural tube fails to close. Explain what impact this has on development of specific brain structures.
3. What is significant about the location of the reading and language areas of the cerebral cortex as shown in [Figure 46.4B](#)?
4. [Key Concept 45.3](#) described the two-point spatial discrimination test. How do the typical results of that test relate to [Figure 46.5B](#)?
5. The brain size of humans is significantly above the regression line for brain size as a function of body size in most other mammals. Why is this observation an understatement of the difference in cerebral cortical capacity in humans as compared with other mammals?

Having briefly described the structure and function of different regions of the nervous system, we will now explore some examples of how information is processed by the neural circuitry in some specific brain regions.

46.2 Nervous System Functions Rely on Neural Circuits

Specific functions are localized in specific parts of the nervous system and depend on the neural circuits, or networks, in those structures. A major focus of modern neuroscience is to understand how the various functions of the nervous system, ranging from simple reflexes to complex learning and memory, are accomplished by the interactions of neurons in circuits. Two extensively studied examples of how neural networks process information are the autonomic nervous system (an output pathway) and the visual system (an input pathway).

focus your learning

To control involuntary autonomic responses, the sympathetic and parasympathetic divisions of the autonomic nervous system have distinct circuitry and typically induce opposite functional responses from target organs and tissues.

Visual information is transduced in the retina via center-surround receptive fields, resulting in patterns of action potential firing in ganglion cells that are transmitted to the visual cortex via the thalamus.

Binocular neurons in the visual cortex receive input from both eyes and thereby enable depth perception in humans.

Pathways of the autonomic nervous system control involuntary physiological functions

The [autonomic nervous system](#), or **ANS**, includes CNS and PNS components and controls many involuntary functions, such as heart rate, blood flow, sweating, and digestive activities. Its control of diverse organs and tissues is crucial to homeostasis. The ANS has two divisions, **sympathetic** and **parasympathetic**, that work in opposition to each other in their effects on most organs (**Figure 46.8**). The sympathetic and parasympathetic divisions are easily distinguished by their anatomy, neurotransmitters, and actions.

autonomic nervous system (ANS) The portion of the peripheral nervous system that controls such involuntary functions as those of guts and glands. Also called the involuntary nervous system.

Figure 46.8 The Autonomic Nervous System The autonomic nervous system is divided into the sympathetic and parasympathetic divisions. The two divisions work in opposition to each other in their effects on most organs; one results in an increase and the other a decrease in activity.

Q: Why does a person get an extremely dry mouth when speaking in public?

The best-known functions of the ANS are those of the sympathetic division that produce the fight-or-flight response: increasing heart rate, blood pressure, and cardiac output and which prepares the body for emergencies (see [Figure 40.3](#)). In contrast, the parasympathetic division slows the heart and lowers blood pressure; its actions have been characterized as “rest and digest.” It is tempting to think of the sympathetic division as speeding things up and the parasympathetic division as slowing things down, but it is not that simple; for example, the sympathetic division slows down the digestive system whereas the parasympathetic division accelerates it.

Whether sympathetic or parasympathetic, every autonomic efferent pathway begins with a cholinergic neuron (that is, a neuron that uses acetylcholine as its neurotransmitter) that has its cell body in the brainstem or spinal cord. These cells are called preganglionic neurons because the second neuron in the pathway with which they synapse resides in a collection of neurons outside the CNS called a **ganglion** (plural *ganglia*). The second neuron is called a postganglionic neuron because its axon extends out from the ganglion. The axon of the postganglionic neuron synapses with cells in the target organs (see [Figure 46.8](#)).

ganglion (gang' glee un) (plural: ganglia) [Gk. lump] A cluster of neurons that have similar characteristics or function.

The postganglionic neurons of the sympathetic division mostly use norepinephrine (also known as noradrenaline) as their neurotransmitter. In contrast, the postganglionic neurons of the parasympathetic division are mostly cholinergic. In organs that receive both sympathetic and parasympathetic input, the target cells respond in an opposite manner to norepinephrine and to acetylcholine. This happens, for example, in a region of the heart called the pacemaker, which initiates the heartbeat. Stimulating the sympathetic nerve to the heart or dripping norepinephrine onto pacemaker cells increases their firing rate and causes the heart to beat faster. In contrast, stimulating the parasympathetic nerve to the heart or dripping acetylcholine onto pacemaker cells decreases their firing rate and causes the heart to beat more slowly (see [Figure 49.7](#)).

The sympathetic and parasympathetic divisions of the ANS can also be distinguished by anatomy. The preganglionic neurons of the parasympathetic division come from the cranial nerves of the brainstem and the sacral (lowest) region of the spinal cord; those of the sympathetic division come from the thoracic and lumbar regions of the spinal cord (see [Figure 46.8](#)). Most of the ganglia of the sympathetic division are lined up and interconnected in two chains, one on either side of the spinal cord. The parasympathetic ganglia are close to the target organs and are not interconnected.

The ANS is an important link between the CNS and many physiological functions. Its control of diverse organs and tissues is crucial to homeostasis. Despite the complexity of the ANS, work by neurobiologists and physiologists over many decades has made it possible to understand its functions in terms of neuronal properties and circuits.

The visual system is an example of information integration by the cerebral cortex

The visual system is one of the most-studied input pathways to the CNS. [Key Concept 45.4](#) described how light falling on the retina produces signals that are transmitted through the cellular circuits of the retina, resulting in action potentials in the optic nerve. But how does the brain use this information to represent the visual world?

RETINAL RECEPTIVE FIELDS

[Key Concept 45.4](#) described how a retinal ganglion cell collects information from several photoreceptors—an example of “convergence of information.” Each ganglion cell is communicating to the brain something more than simply the presence or absence or intensity of light falling on a portion of the retina.

The question of what information the retinal ganglion cell extracts from the photoreceptors was addressed in classic experiments by Stephen Kuffler, then at Johns Hopkins University. He used electrodes to record the activity of single ganglion cells of cat eyes while stimulating their retinas with spots of light ([Figure 46.9](#)). Kuffler's experiments revealed that each ganglion cell has a well-defined [receptive field](#) composed of a group of photoreceptor cells that receive light from a small area of the entire visual field. Stimulating these photoreceptors with light activates the ganglion cell, which sends action potentials to the thalamus and on to the visual cortex (the area of the occipital lobe where visual information is processed; see [Figure 46.4](#)). Information from many photoreceptors is therefore communicated to the brain as a single message. Individual photoreceptors may contribute to the receptive fields of multiple ganglion cells, so that receptive fields overlap.

Original Paper: Kuffler, S. W. 1953. Discharge patterns and functional organization of mammalian retina. *Journal of Neurophysiology* 16: 37–68.

Stephen Kuffler's experiments recorded the activity of single ganglion cells in the eyes of cats. These groundbreaking experiments revealed the existence of a circular receptive field for each of the retina's ganglion cells. Signals from photoreceptor cells in a receptive field are either excitatory or inhibitory to the ganglion cell, which sends action potentials via the optic nerve to the brain.

HYPOTHESIS ▶ Retinal ganglion cells are excited or inhibited by light and dark stimuli falling on local areas of the retina.

METHOD

1. Place electrodes next to an individual retinal ganglion cell.
2. Stimulate the retina with different combinations of light and dark stimuli and record the responses of the ganglion cell.
3. Continue recording and move the stimuli around the retina to find the area of sensitivity—the receptive field—for a specific ganglion cell.

RESULTS

CONCLUSION ▶ Ganglion cells use a center-surround dichotomy to encode patterns of contrast between light and dark.

Q: Why is there a blind spot in each eye?

Figure 46.9 What Does the Eye Tell the Brain?

Q: Why is there a blind spot in each eye?

receptive field The area of visual space that activates a particular cell in the visual system.

The receptive fields of most ganglion cells are circular, but whether a spot of light falling on a receptive field excites or inhibits its ganglion cell depends both on the nature of the receptive field and on where the spot of light falls on it. Receptive fields have a center and a concentric surround, and can be either “on-center” or “off-center.” Light falling on the center of an on-center

receptive field excites the ganglion cell, and light falling on the center of an off-center receptive field inhibits the ganglion cell. Light falling on the surround has the opposite effect: the surround for an on-center receptive field inhibits the ganglion cell, and the surround for an off-center field is excitatory. Thus the activity of the ganglion cell reflects how much of the light stimulus is on the center and how much is on the surround of its receptive field (see [Figure 46.9](#)).

Center effects are always stronger than surround effects. Thus a small dot of light directly on the center of a receptive field has the maximum effect, and a larger light stimulus illuminating the center and parts of the surround has a smaller effect. A uniform patch of light falling equally on the center and surround has very little effect on the firing rate of the ganglion cell for that receptive field. The center and surround almost exactly cancel one another, even though the area of the surround is much larger.

Activity 46.2 Visual Receptive Fields Simulation www.Life11e.com/ac46.2

As is seen in [Figure 46.9](#), photoreceptors synapse onto bipolar cells and bipolar cells onto ganglion cells. This pattern of connectivity describes the relationship between the photoreceptors in the center of a receptive field. The photoreceptors in the surround area modify communication between the center photoreceptors and their bipolar cells through the lateral connections of horizontal cells and amacrine cells. Thus the receptive field of a ganglion cell results from a pattern of synapses between photoreceptors, horizontal cells, amacrine cells, and bipolar cells. A general lesson to learn from this seemingly confusing chain of events is that inhibition can be as important as excitation in neural circuits.

In summary, the neural circuitry of the retina results in the generation of signals in the axons of the optic nerve that communicate simple information about the contrasting patterns of light and dark falling on different parts of the retina. But once the action potentials in the optic nerve reach their destinations, how does the brain integrate them to construct visual images of the outside world?

Animation 46.1 Information Processing in the Retina www.Life11e.com/a46.1

RECEPTIVE FIELDS OF CELLS IN THE VISUAL CORTEX

The axons of the optic nerves terminate in a region of the thalamus that is a relay station receiving information from both the right and left eyes. From the thalamus, the information encoded in the activity of axons in the optic nerves is relayed to the visual cortex in the occipital lobes at the back of the brain. In the 1960s David Hubel and Torsten Wiesel of Harvard University studied the activity of neurons in the visual cortex by shining spots and bars of light on retinas while recording the activities of single cells in the cortex. They found that many neurons in the visual cortex, like retinal ganglion cells, have receptive fields with regions that are mutually antagonistic.

Hubel and Wiesel discovered that neurons in the visual cortex respond selectively to bars of light of different orientations falling on the retina, and in some cases to movement of those bars of light in different directions. The concept that emerges from these experiments is that the brain assembles a mental image of the visual world by analyzing edges in patterns of light falling on the retina. Each retina sends a million axons to the brain, but there are *hundreds of millions* of neurons in the visual cortex. The action potentials from one retinal ganglion cell are received via the thalamus by hundreds of cortical neurons, each responsive to a different combination of orientation, position, color, and movement of contrasting lines in the patterns of light and dark falling on the retina.

Three-dimensional vision results from cortical cells receiving input from both eyes

How do we perceive objects in three dimensions? The short answer is that our two eyes see

overlapping, yet slightly different, visual fields—that is, humans have **binocular vision**. A person who is blind in one eye has difficulty discriminating distances. Animals whose eyes are on the sides of the head rather than facing front have minimal overlap in their fields of vision and, as a result, poor depth vision except for a narrow field straight ahead; however, they can see predators creeping up from all sides.

binocular vision Overlapping visual fields of an animal's two eyes; allows the animal to see in three dimensions.

The story of how the brain integrates information from two eyes begins with the paths of the optic nerves. The two optic nerves run along the underside of the brain, join just under the hypothalamus, and then separate again (**Focus: Key Figure 46.10**). The place where they join is called the **optic chiasm**. Axons from the half of each retina closest to the nose cross in the optic chiasm and go to the opposite side of the brain. The axons from the outer half of each retina do not cross over at the **optic chiasm**; axons from the outer left retina go to the left side of the brain, and vice versa for axons from the outer right retina.

focus: key figure

Figure 46.10 How Do We See in 3-D? **(A)** Our eyes have largely overlapping visual fields, and both eyes transmit information to both sides of the brain. However, because the axons from the inner sides of the retinas cross at the optic chiasm, information from the visual space to the left of straight ahead goes to the right side of the brain, and information from the visual space to the right of straight ahead goes to the left side of the brain. **(B)** Between these left and right eye columns of neurons are neurons that receive input from both eyes. These are the binocular cells. **(C)** Light from objects that are different distances away will fall at different locations on the retinas. These disparities between where the image of the fixation point and the images of other objects fall on the retina means that different binocular cells will

receive input from different retinal axons depending on how far away the object is. These disparity sensitive cells enable depth perception and 3-D vision.

Q: What would be the consequences of an anterior-posterior cut of the optic chiasm on midline?

optic chiasm [Gk. *chiasma*: cross] Structure on the lower surface of the vertebrate brain where the two optic nerves come together.

optic chiasm [Gk. *chiasma*: cross] Structure on the lower surface of the vertebrate brain where the two optic nerves come together.

The functional consequence of the optic chiasm is that all of the visual information from the left side of your field of vision when you are looking straight ahead goes to the right side of your brain, and all of the visual information from the right side of your field of vision goes to the left side of your brain. However, there is a very large area of overlap between the visual fields of the two eyes. These relationships are shown in purple and green in [Figure 46.10](#).

Because of the overlap between the visual fields of the two eyes, there can be neurons in the visual cortex that receive input from both the left and the right eye. These are called binocular cells, and they can detect disparity between where the image of an object falls on the two retinas. What is disparity? Hold your finger out in front of you and look at it closing one eye and then the other. Your finger appears to jump back and forth because its image falls on a different position on each retina. Repeat the exercise with a distant object. It doesn't jump back and forth as much because there is less disparity in the positions of the image on the two retinas. Certain binocular cells respond optimally to a stimulus falling on both retinas with a particular disparity. Which set of binocular cells is stimulated depends on how far away the stimulus is.

When we look at something, we can detect its shape, color, depth, and movement. Where does all this information come together? Is there a single cell that fires only when a red sports car drives by? The answer to that is probably no. Visual experience comes from simultaneous activity in many different cells. In addition, most visual experiences are enhanced by information from the other senses and from memory, which helps explain why about 75 percent of the cerebral cortex is association cortex.

46.2 recap

Information in the nervous system is processed by cellular interactions in neural networks. The opposing actions of the sympathetic and parasympathetic divisions of the ANS can be understood in terms of neural pathways consisting of just two neurons. Vision begins with retinal photoreceptors organized into circular retinal receptive fields that influence the activity of retinal ganglion cells. Information from ganglion cells is transmitted in the optic nerves to the thalamus and relayed from there to the visual cortex. The left visual field from both eyes is represented in the right visual cortex, and vice versa for the right visual field. Receptive fields of cortical cells represent input from multiple ganglion cells, and binocular, disparity-sensitive cortical cells enable depth perception.

learning outcomes

You should be able to:

- Predict the outcome on effector tissues when specific peripheral nerves of the sympathetic

or parasympathetic divisions of the autonomic nervous system are damaged or stimulated.

- Explain how receptive fields are generated in the retina through the interactions between photoreceptors, bipolar cells, and ganglion cells, and through the modulation of their signaling by horizontal and amacrine cells.
 - Understand how neural connections between the eyes and the visual cortex produce three-dimensional vision.
-

1. Explain how a knife wound to left side of the neck can result in pupillary constriction in the left eye.
 2. Why can a small spot of light on the retina cause a larger response in a retinal ganglion cell than a large spot of light falling on the same area of retina?
 3. What changes in vision would occur if the optic chiasm were cut right on the midline?
-

By studying the neural circuitry of the visual system and the ANS, you have gained some understanding of how information reaches the CNS and how the CNS controls various functions of the body. But what about the higher functions of the mammalian CNS—the complex functions between input and output, such as language, learning, memory, and dreams?

46.3 Higher Brain Functions Involve Integration of Multiple Systems

The higher brain functions discussed in the remaining pages of this chapter are undeniably complex. Nevertheless, neuroscientists, using a wide range of techniques, are making considerable progress in understanding these functions in terms of their cellular, molecular, and network properties. The following discussion will address several aspects of brain and behavior that present challenges to neuroscientists: sleep and dreaming, learning and memory, language use, and consciousness.

focus your learning

During wakefulness and REM sleep (dreaming), certain brainstem nuclei provide excitatory input that activates the thalamus and cortex, while in non-REM sleep these nuclei are less active.

Sleep states are divided into slow-wave sleep (non-REM) and REM sleep, and humans alternate between these states four or five times each night.

Sleep deprivation impairs cognitive functions.

Language functions are lateralized (typically within the left cerebral hemisphere). Language ability involves parts of the occipital, parietal, temporal, and frontal lobes.

The cellular correlate for learning and memory is the modification of synaptic strength. The hippocampus is important for acquiring and consolidating declarative memories.

In humans and higher mammals, the insular lobe integrates physiological information to generate a conscious awareness of the self.

Sleep and dreaming are reflected in electrical patterns in the cerebral cortex

A dominant feature of behavior is the daily cycle of sleep and waking. All birds and mammals, probably all other vertebrates, and also many invertebrates, sleep. We humans spend one-third of our lives sleeping, yet we do not know why or how. We do know, however, that we need to sleep. Loss of sleep impairs alertness and performance. Many people in our society—certainly most college students—are chronically sleep-deprived. Accidents and serious mistakes that endanger lives can be attributed to impaired alertness caused by lack of sleep. Insomnia (difficulty in falling or staying asleep) is one of the most common medical complaints.

THE ELECTROENCEPHALOGRAM

A common tool of sleep researchers is the [electroencephalogram](#), or **EEG**. Rather than recording the activity of single neurons, the EEG characterizes activity in huge numbers of neurons. EEG electrodes are much larger than the fine electrodes used to detect single cell activity. Placed at different locations on the head and scalp (**Figure 46.11A**), EEG electrodes record fluctuations in the electric potential differences between electrodes over time. These differences reflect the electrical activity of the neurons in the brain regions under the electrodes, primarily regions of the cerebral cortex. Usually the electrical activity of one or more skeletal muscles is also recorded; this record is called an electromyogram (EMG). Movements of the eyes are recorded as an electrooculogram (EOG).

electroencephalogram (EEG) A graphic recording of electrical potentials from the brain.

Figure 46.11 Stages of Sleep (A) Electrical activity in the cerebral cortex is detected by electrodes that are placed on the head and record changes in voltage between the electrodes through time. (B) The resulting record is an electroencephalogram, or EEG. (C) Humans cycle through different stages of sleep throughout the night

EEG, EMG, and EOG patterns reveal the transition from being awake to being asleep. They also reveal that there are different states of sleep. In mammals other than humans, two major sleep states are easily distinguished: **slow-wave sleep** and **rapid eye movement (REM) sleep**. Slow-wave sleep gets its name from the high-amplitude, slow-frequency waves in the EEG. REM sleep gets its name from jerky movements of the eyeballs that occur during this state. In humans, sleep states are characterized as non-REM sleep and REM sleep. Human non-REM sleep is divided into three stages.

slow-wave sleep See non-REM sleep.

rapid eye movement (REM) sleep A sleep state characterized by vivid dreams, skeletal muscle relaxation, and rapid eye movements. (Contrast with non-REM sleep.)

When you fall asleep, you first enter stage 1 non-REM sleep, which then progresses through stage 2 to stage 3 (**Figure 46.11B**). Stage 3 is deep, restorative, slow-wave sleep. This first full cycle of non-REM sleep is followed by an episode of REM sleep. Throughout the night you experience four or five cycles of non-REM and REM sleep (**Figure 46.11C**). About 80 percent of your sleep is non-REM sleep. The most vivid dreams and nightmares occur during the 20 percent of sleep that is REM sleep.

CELLULAR CHANGES DURING SLEEP

When we are awake, several nuclei (groups of neurons) in the brainstem reticular-activating system are continuously active. Axons from neurons in these nuclei extend to the thalamus and throughout the cerebral cortex, where they release depolarizing neurotransmitters (acetylcholine, norepinephrine, and serotonin). These broadly distributed neurotransmitters keep the resting potential of the neurons of the thalamus and cortex close to threshold and sensitive to synaptic inputs, thereby maintaining the responsiveness of the brain that

characterizes being awake.

With the onset of sleep, activity in these brainstem nuclei decreases, and their axon terminals release less neurotransmitter. With the withdrawal of the depolarizing neurotransmitters, the resting potentials of the cells of the thalamus and cortex become more negative (hyperpolarized), and the cells are less sensitive to excitatory synaptic input. Their processing of information is inhibited, and consciousness is lost. You have probably experienced this as “nodding off.” As you enter non-REM sleep, cells of the cortex begin to fire action potentials in bursts. The synchronization of these bursts over broad areas of cerebral cortex results in the EEG slow-wave pattern that characterizes deep non-REM sleep.

At the transition from non-REM to REM sleep, dramatic changes occur. Some of the brainstem nuclei that were inactive during non-REM sleep become active again, causing a general depolarization of cortical neurons. Thus in REM sleep the synchronized bursts of firing cease, and the EEG resembles that of the awake brain. Because the resting potentials of the neurons return to near threshold levels, the cortex can process information, and vivid dreams occur.

So why don't we act out our dreams? During REM sleep the brain inhibits both afferent (sensory) and efferent (motor) pathways; we are paralyzed during REM sleep. Limb twitches and the jerky eye movements are motor signals breaking through the inhibition. The bizarre nature of dreams may be due to the lack of sensory feedback to the cortex from the body and the outside world. In other words, a functioning cortex is out of touch with reality. The function of muscle paralysis during REM sleep may be to prevent the acting out of dreams.

Knowing the cellular mechanisms of sleep has not yet led to an understanding of its function. Many questions remain. Why do we have two sleep states with very different neurophysiological characteristics? Why does non-REM sleep always occur first? Why do the two states cycle during the rest phase? We know sleep is essential for life, but we don't know why. One set of hypotheses is that sleep is necessary for the maintenance and repair of neural connections and for the neural changes involved in learning and memory—and possibly forgetting. These hypotheses are supported by many experiments showing that performance of a learned task or recall of declarative information on the day following training is impaired if sleep is prevented, and is best following a good night's sleep.

Language abilities are localized in the left cerebral hemisphere

No aspect of brain function is as integrally related to human consciousness and intellect as language. Therefore brain mechanisms that underlie the acquisition and use of language are extremely interesting to neuroscientists. A curious observation about language ability is that it resides in one cerebral hemisphere—which in 97 percent of people is the left hemisphere. This phenomenon is referred to as the [lateralization](#) of language functions.

lateralization A phenomenon in humans in which language functions come to reside in one cerebral hemisphere, usually the left.

Fascinating research on this subject was conducted by Roger Sperry and his colleagues at the California Institute of Technology. The two cerebral hemispheres are connected by a tract of white matter called the corpus callosum. In one severe form of epilepsy, bursts of action potentials causing seizures travel between hemispheres via the corpus callosum. Cutting the tract eliminates the problem, and patients function well following surgery. However, these “split-brain” subjects display interesting deficits in language ability.

After the surgery, if an object is shown in the right visual field and the left eye is closed (see [Figure 46.10](#)), the patient can describe it verbally and in writing. If the object is shown in the left visual field and the right eye is closed, the patient cannot describe it either verbally or in writing, but can use his or her left hand to point to a picture of the object. Without the connecting tissue

between the two hemispheres, knowledge or experience of the right hemisphere can no longer be expressed in language.

Individuals who have suffered damage to the left hemisphere frequently suffer from some form of [aphasia](#), a deficit in the ability to use or understand words. Studies of such individuals have identified several language areas in the left hemisphere.

aphasia A deficit in the ability to use or understand words.

[Broca's area](#), located in the frontal lobe just in front of the primary motor cortex, is essential for speech. Damage to Broca's area results in halting, slow, poorly articulated speech or even complete loss of speech, but the patient can still read and understand language.

Broca's area A portion of the human brain essential for speech. Located in the frontal lobe just in front of the primary motor cortex.

[Wernicke's area](#), located in the temporal lobe close to its border with the occipital lobe, is more involved with sensory than with motor aspects of language. Damage to Wernicke's area can cause a person to lose the ability to speak sensibly while retaining the abilities to form the sounds of normal speech and to imitate its cadence. Such a patient cannot understand spoken or written language.

Wernicke's area A region in the temporal lobe of the human brain that is involved with the sensory aspects of language.

The [angular gyrus](#), located near Wernicke's area, is involved in integrating spoken and written language.

angular gyrus A part of the human brain believed to be essential for integrating spoken and written language.

Normal language ability depends on the flow of information among various areas of the left cerebral cortex. Input from spoken language travels from the auditory cortex to Wernicke's area ([Figure 46.12A](#)). Input from written language travels from the visual cortex to the angular gyrus to Wernicke's area ([Figure 46.12B](#)). Commands to speak are formulated in Wernicke's area and travel to Broca's area and from there to the primary motor cortex. Damage to any one of those areas or the pathways between them can result in aphasia. Using modern methods of brain imaging such as functional magnetic resonance imaging (fMRI) or positron emission tomography (PET), it is possible to see the metabolic activity in different brain areas when the brain is using language ([Figure 46.13](#)).

Speaking words

Generating word associations

Figure 46.13 Imaging Techniques Reveal Active Parts of the Brain Positron emission tomography (PET) scanning reveals the brain regions activated by different aspects of language use. Radioactively labeled glucose is given to the subject. Brain areas take up radioactivity in proportion to their metabolic use of glucose. The PET scan visualizes levels of radioactivity in specific brain regions when a particular activity

is performed. The red and white areas are the most active.

Some learning and memory can be localized to specific brain areas

Learning is the modification of behavior by experience. Memory is the ability of the nervous system to retain what is learned and experienced. Even very simple animals can learn and remember, but these two abilities are most highly developed in humans. Consider the amount of information associated with learning a language, and then the much greater amount of information that language enables our brains to store and to process. The capacity of memory and the rate at which memories can be retrieved are remarkable features of the human nervous system.

Learning that leads to long-term memory and modification of behavior must involve long-lasting synaptic changes. A phenomenon that may explain how long-term synaptic changes might arise is [long-term potentiation](#), or **LTP**. LTP results from high-frequency electrical stimulation of certain identifiable circuits that makes these circuits more sensitive to subsequent stimulation. In contrast, continuous, repetitive, low-level stimulation of these same circuits reduces their responsiveness, a phenomenon that has been called [long-term depression \(LTD\)](#). LTP and LTD may be fundamental cellular or molecular mechanisms involved in learning and memory.

long-term potentiation (LTP) A long-lasting increase in the responsiveness of a neuron resulting from a period of intense stimulation. (Contrast with long-term depression.)

long-term depression (LTD) A long-lasting decrease in the responsiveness of a neuron resulting from a period of prior stimulation. (Contrast with long-term potentiation.)

Above the level of the synapse, memory involves interactions between several brain areas, as we discussed in the opener to this chapter and in Investigating Life: Places Cells Reveal Processes of Memory Consolidation during Sleep. Some of the first insights into memory processes came from surgical treatment of patients with severe seizures. That treatment involves destruction of the excessively active brain area triggering the seizures. To find the right area, the surgery is done under local anesthesia, with the patient remaining conscious. As different regions of the brain are electrically stimulated with electrodes, the patient reports the resulting sensations. Stimulation of some regions of the association cortex elicits recall of vivid memories. Such observations provided the first evidence that specific areas in the brain are associated with specific memories and that memory can be attributed to networks of neurons. Destroying a small area of the brain does not completely erase a memory, however, so it is postulated that memory is a function distributed over many brain regions and can be stimulated via many different routes.

You experience several forms of memory everyday. You have [immediate memory](#) for events that are happening now. Immediate memory is almost perfectly photographic but lasts only seconds. [Short-term memory](#) contains less information but lasts longer—on the order of 10-15 minutes. When you are introduced to a group of several new people, you probably will have forgotten their names in an hour or so if you have not written them down, used them in a conversation, or made a conscious effort to repeat them. Repetition, use, or reinforcement by something that gets your attention (a title such as “President,” for example) facilitates the transfer of short-term memory to [long-term memory](#), which can last for days, months, years, or a lifetime. There is also intermediate-term memory, which lasts about a day.

immediate memory A form of memory for events happening in the present that is almost perfectly photographic, but lasts only seconds. (Contrast with long-term memory, short-term

memory.)

short-term memory Information that is maintained in the brain and can be accessed for a short period of time—seconds to minutes. (Contrast with immediate memory, long-term memory.)

long-term memory Information that is maintained in the brain and is accessible for long periods of time—hours to years. (Contrast with immediate memory, short-term memory.)

Knowledge about neural mechanisms for the transfer of short-term memory to long-term memory—memory consolidation — has come from observations of persons who have lost parts of the limbic system, notably the hippocampus. A famous case is that of the man identified as H.M., whose hippocampus on both sides of the brain was removed to control his severe epilepsy. After the surgery, H.M. was unable to transfer information to long-term memory. If someone was introduced to him, had a conversation with him, and then left the room for several minutes, when that person returned, H.M. did not recognize him—it was as if the conversation had never taken place. Up until his death 55 years later, H.M. remembered events that happened before his surgery but could not remember postsurgery events for more than 10-15 minutes.

The studies of H.M., other such patients, and experiments on animals and even London taxi drivers show that the hippocampus plays an essential role in the acquisition of **declarative memories**—those that involve people, places, things, and events. The study featured in the opener to this chapter revealed the mapping of spatial information by neural networks in the rat, and the replay of that information when the rat is resting before or after running a maze. Subsequent experiments revealed the replay of the same spatial information during sleep, possibly revealing a process that is consolidating the memory and transferring it into long-term storage (see Investigating Life: Place Cells Reveal Processes of Memory Consolidation during Sleep).

Media Clip 46.1 **The Man with No Short-Term Memory** www.Life11e.com/mc46.1

We still cannot answer the question “What is consciousness?”

This chapter has only scratched the surface of the organization and functions of the human brain. Even with all of our knowledge of the human brain, and with all of the sophisticated new research tools, we still cannot answer the question “What is consciousness?”

The word “consciousness” is used in everyday language to refer to being awake in contrast to being asleep or in a coma. Here we are referring to being mentally aware of yourself, your environment, and events going on around you in such a way that you can plan for future events and make decisions based on experience, evidence, value systems, and predicted consequences. Speculations about consciousness have been the realm of philosophers, but we are getting closer to a neurobiological understanding.

One requirement for conscious experience is a perception of self that can be integrated with information from the physical and social environment and information from past experience. The basis for a perception of self derives from the huge amount of somatosensory and visceral information that comes from all parts of the body. This information is used for motor control and for homeostatic regulation. It enables animals to find food, seek mates, seek warmth, avoid cold, avoid danger, and so on. Different types of this afferent information go to appropriate control and regulatory systems in the brainstem and forebrain. But these diverse sources of information also go to the insular cortex. The insular lobe appears to integrate physiological information from all over the body to create a sensation of how the body “feels.” Thus when an animal’s actions restore homeostasis, it “feels” better, and this is motivation to do the right thing for well-being.

In humans and the great apes, the insular cortex is greatly expanded and its circuitry

communicates with parts of the brain involved in planning and decision making. In imaging studies, the insular lobe is activated by a great diversity of situations that involve strong feelings such as pleasure, disgust, humor, pain, lust, craving, humiliation, guilt, or empathy. Damage to the insular lobe causes apathy, loss of the ability to enjoy music, loss of sexual responsiveness, and even loss of the ability to distinguish good food from spoiled food. Humans and the few other species (great apes, elephants, and some marine mammals) that have an expanded insular lobe are the only species that can recognize themselves in a mirror. Could it be that this very discrete part of our brains and its circuitry are the neurobiological basis for self-awareness?

46.3 recap

Complex functions of the nervous system can be understood in terms of the properties of neurons and neural networks. Language functions are lateralized to the left cerebral hemisphere. So, since information about objects seen in the left visual field is processed in the right visual cortex, cannot be described in words, but they can be drawn. Imaging shows the integration of different brain areas in the hearing, reading, and speaking of words. REM and non-REM sleep and awake states involve very different activities in many areas of the brain. Sleep states have a regular organization of expression during the daily rest phase. At the cellular level, learning and memory involve changes in synaptic strength, and memory processes involve interactions of neural networks from different brain areas. Declarative memories are acquired through the hippocampus. Consciousness may involve creation of a perception of the self in the insular cortex.

learning outcomes

You should be able to:

- Recognize the characteristic EEGs associated with wakefulness, non-REM sleep, and REM sleep, and infer which brain areas are active during these distinct phases of the sleep-wake cycle.
- Describe the flow of information when speaking a written or a heard word, and specify which areas of the brain are involved in speech processing.
- Connect the modification of synaptic strength in place cells to the development of a spatial map in the hippocampus.
- Connect evolutionary changes in brain structures to the development of self-awareness.

1. What is the significance of paralysis of skeletal muscles during REM sleep?
2. If a person with a severed corpus callosum is shown an object in his left visual field, how will he be able to communicate to an observer what that object is?
3. What does the case of H.M. tell us about the brain mechanisms underlying the acquisition of declarative memories?
4. What is unique about the insular lobes of higher mammals that may explain the evolution of consciousness?

Can recordings of place cells reveal processes of memory consolidation during sleep?

Unfortunately we cannot give a rat an exam to ask what it remembers. However, we can look in other brain areas for electrophysiological patterns of activity that correlate with the hippocampal place-cell patterns. Wilson and colleagues described the fast replay of the hippocampal place-cell patterns as a unique EEG signal called “ripples.” They observed that these ripples were tightly coupled to slower EEG brainwaves that spread to cortical areas of the brain. When they recorded in some of those other areas—the frontal cortex and the visual cortex—they found similar patterns of firing (i.e., ripples) in those areas that were synchronized to the hippocampal ripples. They hypothesized that the ripples represent memory transcripts that are transferred to and stored in areas of the cortex.

Future directions

The neurophysiological studies of the acquisition and consolidation of declarative memories bring us closer to understanding the physical nature of a memory. The synaptic strengthening known as LTP (long-term potentiation) lasts a long time in contrast to action potentials, but not nearly as long as a memory that can virtually last a lifetime. We can think of a memory as a piece of information that is stored in the brain. We have used the word “information” a lot in this chapter, but we really do not know what “information” is in the brain. It is not simply action potentials; they are brief, transient events. It is not patterns of synapses; they are constantly being altered. It must involve patterns of connectivity in and between neural networks in the brain; but what maintains those networks over years? We have much to learn about how our brains work.

▶ 46.1 Functions Are Localized in the Nervous System

- The brain and spinal cord make up the [central nervous system \(CNS\)](#); the cranial and spinal nerves make up the [peripheral nervous system \(PNS\)](#).

central nervous system (CNS) That portion of the nervous system that is the site of most information processing, storage, and retrieval; in vertebrates, the brain and spinal cord. (Contrast with peripheral nervous system.)

peripheral nervous system (PNS) The portion of the nervous system that transmits information to and from the central nervous system, consisting of neurons that extend or reside outside the brain or spinal cord and their supporting cells. (Contrast with central nervous system.)

- The nervous system can be modeled conceptually in terms of the direction of information flow and whether we are conscious of the information. The [afferent](#) component of the PNS carries information from sensory cell receptors to the CNS, and the [efferent](#) component of the PNS carries information from the CNS to the target tissues and organs that are being controlled. **Review** [Figure 46.1](#)

afferent (af' ur unt) [L. *ad*: toward + *ferre*: to carry] Carrying to, as in neurons that carry impulses to the central nervous system (**afferent neurons**), or a blood vessel that carries blood to a structure (**afferent arterioles**). (Contrast with efferent.)

efferent (ef' ur unt) [L. *ex*: out + *ferre*: to bear] Carrying outward or away from, as in neurons that carry impulses outward from the central to the peripheral nervous system (**efferent neurons**), or a blood vessel that carries blood away from a structure (**efferent arterioles**). (Contrast with afferent.)

- The vertebrate nervous system develops from a hollow dorsal neural tube. The brain forms from three swellings at the anterior end of the neural tube, which become the [hindbrain](#), the [midbrain](#), and the [forebrain](#). The developing forebrain consists of the [telencephalon](#) and the [diencephalon](#). The telencephalon develops into the [cerebrum](#) ([cerebral hemispheres](#)). The underlying diencephalon develops into the [thalamus](#) and [hypothalamus](#). The midbrain and hindbrain develop into the [brainstem](#) and the [cerebellum](#). **Review** [Figure 46.2](#)

hindbrain The region of the developing vertebrate brain that gives rise to the medulla, pons, and cerebellum. (Compare with forebrain, midbrain.)

forebrain The region of the vertebrate brain that comprises the cerebrum, thalamus, and hypothalamus. (Compare with hindbrain, midbrain.)

telencephalon The outer, surrounding structure of the embryonic vertebrate forebrain, which develops into the cerebrum.

diencephalon The portion of the vertebrate forebrain that develops into the thalamus and hypothalamus.

cerebrum (su ree' brum) [L. brain] The dorsal anterior portion of the forebrain, making up the largest part of the brain of mammals; the chief coordination center of the nervous system and the major information-processing areas of the vertebrate brain consists of two cerebral hemispheres.

cerebral hemispheres The bilateral divisions of the cerebrum.

thalamus [Gk. *thalamos*: chamber] A region of the vertebrate forebrain; involved in integration of sensory input.

hypothalamus The part of the brain lying below the thalamus; it coordinates water balance, reproduction, temperature regulation, and metabolism.

brain The centralized integrative center of a nervous system.

cerebellum (sair uh bell' um) [L. diminutive of *cerebrum*: brain] The brain region that controls muscular coordination; located at the anterior end of the hindbrain.

- The spinal cord communicates information between the brain and the rest of the body.
- The **reticular-activating system** is a complex network that directs incoming information to appropriate brainstem **nuclei** that control autonomic functions, and transmits information to the forebrain that results in conscious sensation. The reticular-activating system controls the level of arousal of the nervous system, including sleep and wakefulness.

reticular-activating system [L. *reticulum*: net] A central region of the vertebrate brainstem that includes complex fiber tracts conveying neural signals between the forebrain and the spinal cord, with collateral fibers to a variety of nuclei that are involved in autonomic functions, including arousal from sleep.

- The **limbic system** is a complex set of phylogenetically old forebrain structures involved in emotions, mood, physiological drives (such as hunger and thirst), instincts, and memory. **Review Figure 46.3**

limbic system A group of evolutionarily primitive structures in the vertebrate telencephalon that are involved in emotions, drives, instinctive behaviors, learning, and memory.

- The cerebral hemispheres are the dominant structures of the human brain. Their surfaces are layers of neurons called the **cerebral cortex**. The cerebral hemispheres can be divided into the **temporal, frontal, parietal, occipital, and insular lobes**. Many motor functions are localized in parts of the frontal lobe. Information from many sensory receptors projects to a region of the parietal lobe. Visual information projects to the occipital lobe, and auditory information projects to a region of the temporal lobe. The insular cortex integrates much information about the physiological state of the body, but it is also activated by psychological and emotional conditions and may be responsible for the sense of self. **Review Figures 46.4, 46.5, Activity 46.1**

cerebral cortex The thin layer of gray matter (neuronal cell bodies) that overlies the cerebrum.

insular lobe A region of the cerebrum that folds in between the temporal lobes and the overlying frontal and parietal lobes.

► 46.2 Nervous System Functions Rely on Neural Circuits

- The **autonomic nervous system (ANS)** controls the physiological function of organs and

organ systems. Its **sympathetic** and **parasympathetic** divisions are characterized by their anatomy, neurotransmitters, and effects on target tissues. **Review Figure 46.8**

autonomic nervous system (ANS) The portion of the peripheral nervous system that controls such involuntary functions as those of guts and glands. Also called the involuntary nervous system.

parasympathetic nervous system The division of the autonomic nervous system that works in opposition to the sympathetic nervous system. (Contrast with sympathetic nervous system.)

- The neural network of vision involves patterns of light falling on **receptive fields** in the retina. Receptive fields have a center and a surround, which have opposing effects on ganglion cell firing. **Review Figure 46.10, Activity 46.2, Animation 46.1**

receptive field The area of visual space that activates a particular cell in the visual system.

- Information from retinal ganglion cells is communicated via the optic nerve to the thalamus and then to the visual cortex. The visual cortex seems to assemble an image of the visual world by analyzing edges of patterns of light.
- **Binocular** vision is possible because information from both eyes is communicated to binocular cells in the visual cortex. These cells interpret distance by measuring the disparity between where the same stimulus falls on the two retinas. **Review Focus: Key Figure 46.10**

▶ 46.3 Higher Brain Functions Involve Integration of Multiple Systems

- Humans have a daily cycle of sleep and waking. Sleep can be divided into **rapid eye movement (REM) sleep** and non-REM sleep. Deep non-REM sleep is known as **slow-wave sleep** because of its characteristic EEG patterns. **Review Figure 46.11**

slow-wave sleep See non-REM sleep.

- Language abilities are localized mostly in the left cerebral hemisphere, a phenomenon known as **lateralization**. Different areas of the left hemisphere—including **Broca's area**, **Wernicke's area**, and the **angular gyrus**—are responsible for different aspects of language. **Review Figures 46.12, 46.13, Activity 46.3**

lateralization A phenomenon in humans in which language functions come to reside in one cerebral hemisphere, usually the left.

angular gyrus A part of the human brain believed to be essential for integrating spoken and written language.

- Some learning and memory processes can be localized to specific brain areas. Long-lasting changes in synaptic properties referred to as **long-term potentiation (LTP)** and **long-term depression (LDP)** may be involved in learning and memory.

long-term potentiation (LTP) A long-lasting increase in the responsiveness of a neuron resulting from a period of intense stimulation. (Contrast with long-term depression.)

long-term depression (LTD) A long-lasting decrease in the responsiveness of a neuron

resulting from a period of prior stimulation. (Contrast with long-term potentiation.)

- Complex memories can be elicited by stimulating small regions of association cortex. Damage to the hippocampus can destroy the ability to form long-term [declarative memory](#).

declarative memory Memory of people, places, events, and things that can be consciously recalled and described.

- A sense of the physiological state of the body may be created in the insular cortex from visceral afferent information. Evolution of this integrative function in humans and other higher primates could be the basis for conscious experience.

See [Activity 46.4](#) for a concept review of this chapter.

► Apply What You’ve Learned

Review

- 6.1 Specific areas within the five lobes of the cerebral cortex have sensory, motor, and associative functions.
- 6.3 Sleep deprivation impairs cognitive functions.
- 6.3 Language functions are lateralized (typically within the left cerebral hemisphere). Language ability involves parts of the occipital, parietal, temporal, and frontal lobes.

Original Paper: Chee, M. W. L., L. Y. M. Chuah, V. Venkatraman, W. Y. Chan, P. Philip and D. F. Dinges. 2006. Functional imaging of working memory following normal sleep and after 24 and 35 h of sleep deprivation: Correlations of fronto-parietal activation with performance. *Neuroimage* 31: 419-428.

Insufficient sleep has negative consequences. There are the physiological ones: lack of energy, difficulty staying awake, and even high blood pressure, diabetes, and stroke. And what about cognitive abilities—functions such as memory and alertness? Looking for answers, researchers ran tests on three groups of subjects. In the first group, subjects were rested and wakeful. This “RW” group was compared with subjects who were sleep-deprived for 24 hours (“SD24”) and subjects who were sleep-deprived for 35 hours (“SD35”). The researchers looked at both alertness and working memory (the ability to hold new information in memory for a short time to enable cognitive processing). They also performed brain scans, using magnetic resonance imaging (MRI), to see what specific areas of the brain were affected by sleep deprivation.

In one test (referred to as the LTR test), subjects looked at a picture of four capital letters for 0.5 seconds. Three seconds later they were shown a lowercase letter for 1.5 seconds and were to press a button if the lowercase letter matched one of the capital letters they had just seen.

The second test (referred to as the PLUS test) required more cognitive processing than the LTR test. In the PLUS test, subjects looked at a picture of two capital letters for 0.5 seconds. Three seconds later they were shown a lowercase letter for 1.5 seconds and were to press a button if this was the next letter, in alphabetical sequence, after either of the two capital letters.

The effect of sleep deprivation on working memory was measured by the accuracy of responses of sleep-deprived (SD) subjects compared with rested and wakeful (RW) subjects. The alertness of the SD and RW subjects was measured by their reaction times in milliseconds. The results are shown in the table. Asterisks (*) indicate significant differences between RW and SD subjects.

Using MRI, the researchers measured activation of different brain regions during the testing. Two areas with the most significant differences between RW and SD subjects are shown in the graph. Plus signs (+) indicate significant differences between RW and SD24 subjects; hashtags (#) indicate significant differences between RW and SD35 subjects.

Accuracy (%)	RW	SD24	SD35	Reaction time (ms)	RW	SD24	SD35
LTR	95.2	86.5*	85.0*	LTR	745	792*	769
PLUS	95.0	86.6*	84.3*	PLUS	698	747*	746*

Questions

1. Based on the data in the table, justify the conclusion that sleep deprivation impairs working memory.
2. One interpretation of the reaction-time data in the table is that they reflect decreased alertness after sleep deprivation. What information would lead to this conclusion? What is another way to explain the results?
3. Based on the information in the text, explain why the areas of the cerebral cortex shown in the graph were more affected by sleep deprivation than most other areas of the cerebral cortex examined in this study.
4. After looking at the MRI data, the researchers concluded that sleep deprivation has a stronger effect on the parietal lobe than on the frontal lobe. How do the data support that conclusion? What statistical comparison would you use to test this conclusion?

Musculoskeletal Systems

Relative to their size, many animals have more impressive jumping skills than humans. This red-legged frog (*Rana aurora*) can leap distances up to 20 times its body length.

key concepts

[17.1 Interactions of Actin and Myosin Cause Muscles to Contract](#)

[17.2 Many Factors Affect Muscle Performance](#)

[17.3 Muscles and Skeletal Systems Work Together](#)

Champion Jumpers

The women's long jump Olympic record is 7.4 meters, set in 1988 by Jackie Joyner-Kersey. Another world-record long jump was set two years earlier by Rosie the Ribeter, who jumped 6.5 meters. Rosie was a frog competing in the Calaveras County Jumping Frog Contest. Rosie's jump is actually more impressive—it was 20 times her body length, whereas Jackie's was 5 times her body length. And Rosie jumped from a sitting, crouched position, while Jackie's jump was propelled by a sprint.

Both jumps were powered by skeletal muscle. The cellular mechanisms of muscle contraction are the same in the frog and the human, so why is the frog's jump more impressive? The answer involves the concept of leverage, which depends on the muscles and skeletal elements working together. Muscles pull on bones that are connected at joints to make levers. With a lever you can use the same force to move a large mass a small distance or a small mass a large distance. The ratio of leg length to body mass is greater for the frog than for the human. Thus the frog's long legs can move its small body mass a long distance.

The power for the frog's jump comes from a single contraction of its leg muscles (there is no sprint), and those muscles contract only a very short distance compared to the length of the jump. One species of frog, *Rana pipiens*, has a body length of only 11 centimeters. It has much longer legs, but muscles that power its jump are only about 3.5 centimeters long and shorten by just 0.75 centimeters (21%) when the frog jumps. Once again leverage comes into play. The thigh muscles are attached to the lower leg bones close to the knee joint, thus they can move the opposite ends of those bones over a longer distance and more quickly than if they were attached farther away from the joint. There is a trade-off, however, in terms of force and speed. To use a shovel, you have one hand near the end of the shaft and the other hand farther down the shaft. With hands close together, you can move the shovel blade fast, but not pick up a heavy load of dirt. With hands farther apart, you can't move the blade as fast, but you can pick up a heavier load.

What adaptations optimize the jumping muscles of the frog?

47.1 Interactions of Actin and Myosin Cause Muscles to Contract

Most behavior and many physiological actions of animals, such as beating of the heart and moving of food through the digestive tract, depend on muscle contraction. Wherever tissues contract, muscle cells are responsible. As introduced in [Key Concept 39.1](#) and shown in [Figure 39.2](#), there are three types of vertebrate muscle:

- [Skeletal muscle](#) is responsible for all voluntary movements, such as running or playing a piano. It is also involved in many involuntary actions, including breathing, shivering, and maintaining posture.

skeletal muscle A type of muscle tissue characterized by multinucleated cells containing highly ordered arrangements of actin and myosin microfilaments. Also called striated muscle. (Contrast with cardiac muscle, smooth muscle.)

- [Cardiac muscle](#) is responsible for the beating of the heart.

cardiac muscle A type of muscle tissue that makes up, and is responsible for the beating of, the heart. Characterized by branching cells with single nuclei and a striated (striped) appearance. (Contrast with smooth muscle, skeletal muscle.)

- [Smooth muscle](#) creates movement in many hollow internal organs, such as the digestive system, bladder, and blood vessels, and is under the control of the autonomic (involuntary) nervous system.

smooth muscle Muscle tissue consisting of sheets of mononucleated cells innervated by the autonomic nervous system. (Contrast with cardiac muscle, skeletal muscle.)

focus your learning

When skeletal muscle contracts, the sarcomeres shorten and the band pattern changes.

Muscle contraction is due to repeated cross bridge forming, breaking, and reforming between the actin and myosin filaments causing them to slide past each other.

Action potentials arriving at a neuromuscular junction trigger action potentials in the muscle cell membrane, resulting in release of Ca^{2+} from the sarcoplasmic reticulum.

Cardiac muscle has similarities and differences with skeletal muscle that are important for their respective functions.

Skeletal and smooth muscle occur in all animal phyla, but cardiac muscle is unique to vertebrates. All three muscle types share the same underlying molecular mechanisms for generating force. We will use vertebrate skeletal muscle as our primary example. Later in this section we will discuss the differences in cardiac and smooth muscle that adapt them to their

particular functions, and at the end of [Key Concept 47.2](#) we will describe some interesting specializations of insect muscle.

Sliding filaments of actin and myosin cause skeletal muscle to contract

Skeletal muscle is also called striated muscle—striated because of its striped appearance ([Figure 47.1](#); also see [Figure 39.2](#)) and skeletal because its attachments to skeletal elements make most movements of the body possible. Skeletal muscle cells, called muscle fibers, are large and long and have many nuclei.

Figure 47.1 The Structure of Skeletal Muscle A skeletal muscle is made up of bundles of muscle fibers. Each muscle fiber is a multinucleate cell containing numerous myofibrils, which are highly ordered assemblages of thick myosin and thin

actin filaments. The arrangement of the actin and myosin filaments gives skeletal muscle fibers their characteristic striated appearance.

Activity 47.1 The Structure of a Sarcomere www.Life11e.com/ac47.1

These multinucleate cells form in development through the fusion of many individual embryonic muscle cells called myoblasts. A specific muscle such as your biceps (which bends your arm) is composed of hundreds or thousands of muscle fibers bundled together by connective tissue.

Muscle contraction is due to the interaction between the contractile proteins **actin** and **myosin**. Within muscle cells, **actin** and myosin molecules are organized into filaments. Actin filaments are also called thin filaments, and myosin filaments are called thick filaments. The two kinds of filaments lie parallel to each other. When muscle contraction is triggered, the actin and myosin filaments slide past each other in a telescoping fashion.

actin [Gk. *aktis*: ray] A protein that makes up the cytoskeletal microfilaments in eukaryotic cells and is one of the two contractile proteins in muscle. (See *also* myosin.)

myosin One of the two contractile proteins of muscle. (See *also* actin.)

What is the relationship between a skeletal muscle fiber and the actin and myosin filaments responsible for its contraction? Each muscle fiber (cell) is packed with **myofibrils**—bundles of thin actin and thick myosin filaments arranged in orderly fashion. In most regions of the myofibril, each thick myosin filament is surrounded by six thin actin filaments, and each thin actin filament sits within a triangle of three thick myosin filaments.

myofibril (my' oh fy' bril) [Gk. *mys*: muscle + L. *fibrilla*: small fiber] A polymeric unit of actin or myosin in a muscle.

A longitudinal view of a myofibril reveals why skeletal muscle appears striated. The myofibril consists of repeating units called **sarcomeres**. Each sarcomere is made of overlapping filaments of actin and myosin, which create a distinct banding pattern (see [Figure 47.1](#)). Before the molecular nature of the muscle banding pattern was known, the bands were given names that are still used today. Each sarcomere is bounded by Z lines, which anchor the thin actin filaments. Centered in the sarcomere is the A band, which contains all the myosin filaments. The H zone and the I band, which appear light, are regions where actin and myosin filaments do not overlap in the relaxed muscle. The dark stripe within the H zone is called the M band; it contains proteins that hold the myosin filaments in their regular arrangement.

sarcomere (sark' o meer) [Gk. *sark*: flesh + *meros*: unit] The contractile unit of a skeletal muscle.

The bundles of myosin filaments are held in a centered position within the sarcomere by a protein called **titin** (see [Figure 47.2](#)). Titin is the largest protein in the body; it runs the full length of the sarcomere from Z line to Z line. Each titin molecule runs right through a myosin bundle. Between the ends of the myosin bundles and the Z lines, titin molecules are very stretchable, like bungee cords. In a relaxed skeletal muscle, resistance to stretch is mostly due to the elasticity of the titin molecules.

titin A protein that holds bundles of myosin filaments in a centered position within the sarcomeres of muscle cells. The largest protein in the human body.

As the muscle contracts, the sarcomeres shorten and the band pattern changes. The H zone and the I band become much narrower, and the Z lines move toward the A band as if the actin filaments were sliding into the H zone, the region occupied by the myosin filaments (**Figure 47.2**). In the mid-1950s this observation independently led two teams of British biologists to propose the **sliding filament model** of muscle contraction.

sliding filament model Mechanism of muscle contraction based on the formation and breaking of crossbridges between actin and myosin filaments, causing the filaments to slide together.

Figure 47.2 Sliding Filaments The banding pattern of the sarcomere changes as it shortens, as seen in electron micrographs. These observations led to the sliding filament model of muscle contraction.

It is not uncommon in science for critical breakthroughs to be made simultaneously in different laboratories, but in this case the coincidences are remarkable. The leaders of the two teams were named Hugh Huxley and Andrew Huxley—but they were not related. Andrew Huxley was a faculty member at Cambridge University in the early 1950s, and Hugh Huxley was a graduate student working in a different laboratory. Both were interested in the structure of muscle and the mechanism of contraction. Hugh Huxley moved to MIT as a postdoctoral fellow where he worked with Jean Hanson using electron microscopy. Andrew Huxley, joined by Rolf Niedergerke, used a new form of light microscopy that he and Huxley developed. The two groups proposed the sliding filament model at the same time, and both papers were published in the same issue of the journal *Nature*.

Actin-myosin interactions cause filaments to slide

To understand the mechanism causing the actin and myosin filaments to slide past each other, we must first examine the structures of actin and myosin (**Figure 47.3**). A myosin molecule consists of two long polypeptide chains coiled together, each ending in a large globular head. A

myosin filament is made up of many myosin molecules arranged in parallel, with their heads projecting sideways at each end of the filament like a bunch of golf clubs.

Figure 47.3 Actin and Myosin Filaments Overlap to Form Myofibrils Myosin filaments are bundles of molecules with globular heads and polypeptide tails; the protein titin holds these filaments centered within the sarcomeres. Actin filaments consist of two chains of actin monomers twisted together. They are wrapped by chains of the polypeptide tropomyosin and are studded at intervals with another protein, troponin.

Animation 47.1 **Molecular Mechanisms of Muscle Contraction** www.Life11e.com/a47.1

An actin filament consists of actin monomers polymerized into long chains that look like two strands of beads twisted together. Twisting around the actin chains is another protein, **tropomyosin**, and attached to tropomyosin at intervals are molecules of **troponin**. We'll discuss these two proteins in more detail later in this section.

tropomyosin [troe poe my' oh sin] One of the three protein components of an actin filament; controls the interactions of actin and myosin necessary for muscle contraction.

troponin One of the three components of an actin filament; binds to actin, tropomyosin, and Ca^{2+} .

The myosin heads can bind specific sites on actin, to form crossbridges between the myosin and the actin filaments. Moreover, when a myosin head binds to an actin filament, the head's conformation changes. As the head bends, it exerts a tiny force that causes the actin filament to move 5-10 nanometers relative to the myosin filament. When the myosin heads are bound to actin, they can bind and hydrolyze ATP. The energy released when this happens changes the conformation of the myosin head, causing it to release the actin and return to its extended position, from which it can bind to actin again.

Together these details explain the cycle of events that cause the actin and myosin filaments to slide past each other and shorten the sarcomere. They also explain rigor mortis—the stiffening of muscles soon after death. ATP binding causes myosin to release from actin, so when ATP production stops with death, myosin cannot release and the muscles stay contracted. Eventually, however, the proteins lose their integrity and the muscles soften. The timing of these events helps a medical examiner estimate the time of death.

We have been discussing the cycle of contraction in terms of a single myosin head. Remember that each myosin filament has many myosin heads at both ends and is surrounded by six actin filaments; thus the contraction of the sarcomere involves a great many cycles of interaction between actin and myosin molecules. That is why when a single myosin head breaks its contact with actin, the actin filaments do not slip backward.

Actin-myosin interactions are controlled by calcium ions

Like neurons, muscle cells are excitable—that is, their cell membranes generate and conduct action potentials. Action potentials are initiated in skeletal muscle fibers by motor neurons arriving at **neuromuscular junctions** (see [Key Concept 44.3](#)). The axon terminals of motor neurons are generally highly branched and form synapses with hundreds of muscle fibers (**Figure 47.4**). A motor neuron and all of the fibers with which it synapses constitute a **motor unit**. The fibers contract simultaneously when the unit's motor neuron fires. One muscle can consist of many motor units. Thus there are two ways to increase a muscle's strength of contraction—increase the firing rate of an individual motor neuron, or recruit more motor neurons.

neuromuscular junction Synapse (point of contact) where a motor neuron axon stimulates a muscle fiber cell.

motor unit A motor neuron and the muscle fibers it controls.

Figure 47.4 The Neuromuscular Junction Axons branching from a single motor neuron end in terminals that innervate multiple skeletal muscle fibers.

Q: Is there a relationship between the number of fibers that a motor neuron innervates and fine motor control, or between the number of fibers innervated and the exertion of force?

When an action potential arrives at a neuromuscular junction, the neurotransmitter acetylcholine is released from the motor neuron terminals, diffuses across the synaptic cleft, binds to receptors in the postsynaptic membrane, and causes ion channels in the motor end plate to open (see [Figure 44.11](#)). Most of the ions that flow through these channels are Na^+ , and therefore the motor end plate is depolarized. The depolarization spreads to the surrounding cell membrane of the muscle fiber, which contains voltage-gated sodium channels. When threshold is reached, the cell membrane fires an action potential that is conducted rapidly to all points on the surface of the muscle fiber.

An action potential in a muscle fiber also travels deep within the cell. The cell membrane is continuous with a system of **T tubules** that descend into the muscle fiber cytoplasm (also called the **sarcoplasm**). The “T” stands for “transverse.” The contents of the T tubules are outside the cell. The T tubules are like the indentations created in a water-filled balloon by poking your

finger into it. The action potential that spreads over the cell membrane also spreads through this system of T tubules ([Figure 47.5](#)).

T tubules A system of tubules that runs throughout the cytoplasm of a muscle fiber, through which action potentials spread.

sarcoplasm The cytoplasm of a muscle cell.

Figure 47.5 T Tubules Spread Action Potentials into the Fiber An action potential at the neuromuscular junction spreads throughout the muscle fiber via a network of T tubules, triggering the release of Ca^{2+} from the sarcoplasmic reticulum.

Activity 47.2 The Neuromuscular Junction www.Life11e.com/ac47.2?

The T tubules come very close to the endoplasmic reticulum (ER) of the muscle cell. In muscle cells the ER is called the [sarcoplasmic reticulum](#), and it is a closed compartment surrounding every myofibril. Calcium pumps in the sarcoplasmic reticulum take up Ca^{2+} from the sarcoplasm. Therefore when the muscle fiber is at rest, there is a high concentration of Ca^{2+} in the sarcoplasmic reticulum and a very low concentration of Ca^{2+} in the sarcoplasm.

sarcoplasmic reticulum The endoplasmic reticulum of a muscle cell.

Spanning the space between the membranes of the T tubules and the membranes of the sarcoplasmic reticulum are two proteins. One protein, the dihydropyridine (DHP) receptor, is located in the T tubule membrane; it is voltage-sensitive and changes its conformation in response to an action potential spreading through the T tubule system. The other protein, the ryanodine receptor, is located in the sarcoplasmic reticulum membrane and is a Ca^{2+} channel. These two proteins are physically connected. When the DHP receptor changes its conformation due to an action potential, it causes Ca^{2+} to flow through the ryanodine receptor from the sarcoplasmic reticulum to the sarcoplasm. Ca^{2+} ions diffusing through the sarcoplasm surrounding the actin and myosin filaments trigger the interaction of actin and myosin and the sliding of the filaments. How do the Ca^{2+} ions do this?

An actin filament, as you have seen, is a helical arrangement of actin monomers. Twisted around the actin filament are two strands of the protein tropomyosin (**Focus: Key Figure 47.6**; see also [Figure 47.3](#)). At regular intervals, the filament also includes a globular protein, troponin. The troponin molecule has three subunits: one binds actin, one binds tropomyosin, and one binds Ca^{2+} .

focus: key figure

Figure 47.6 Release of Ca^{2+} from the Sarcoplasmic Reticulum Triggers Muscle Contraction When Ca^{2+} binds to troponin, it changes the conformation of troponin, exposing myosin-binding sites on the actin. As long as binding sites and ATP are available, the cycle of actin and myosin interactions continues and the filaments slide past each other. Note that in the relaxed condition, the myosin heads are energized.

Q: What are three roles played by ATP in skeletal muscle contraction?

When the muscle is at rest, the tropomyosin strands are positioned so that they block the myosin-binding sites on the actin filaments. When Ca^{2+} is released into the sarcoplasm, it binds to troponin, changing its conformation. Because the troponin is bound to the tropomyosin, this conformational change twists the tropomyosin enough to expose the actin-myosin binding sites, and the cycle of making and breaking actin-myosin bonds is initiated. The filaments pull past each other, and the muscle fiber contracts. When the calcium pumps in the sarcoplasmic reticulum membranes remove the Ca^{2+} ions from the sarcoplasm, the conformation of the tropomyosin reverts and again blocks the binding of myosin heads to actin, and the muscle fiber returns to its resting condition. [Figure 47.6](#) summarizes this cycle.

Cardiac muscle is similar to and different from skeletal muscle

Like skeletal muscle, cardiac muscle appears striated because of the regular arrangement of actin and myosin filaments into sarcomeres ([Figure 47.7](#)). The difference between cardiac and skeletal muscle is that cardiac muscle cells are smaller and have only one nucleus each (uninucleate). Cardiac muscle cells branch, and the branches of adjoining cells interdigitate, forming a meshwork resistant to tearing. As a result, the heart walls can withstand high pressures while pumping blood, without the danger of developing leaks. Adding to the strength

of cardiac muscle are [intercalated discs](#) that provide strong mechanical adhesions between adjacent cells. Gap junctions are an important feature of cardiac muscle. These structures in the intercalated discs allow cytoplasmic continuity between cells (see [Figure 7.16](#)). Because of gap junctions, cardiac muscle cells are electrically coupled. An action potential initiated at one point in a sheet of cardiac muscle spreads rapidly, causing a large number of cardiac muscle cells to contract simultaneously.

intercalated discs Structural features of cardiac muscle cells that connect cells together and provide electrical continuity through gap junctions.

Figure 47.7 Cardiac Muscle Cells Form a Strong Meshwork Cardiac muscle cells branch and interdigitate, forming a tear-resistant mesh that can withstand the blood pressure generated by the contraction of the heart muscle.

Certain cardiac muscle cells are specialized for generating and conducting electric signals. These pacemaker and conducting cells have a low density of actin and myosin filaments, but they initiate and coordinate the rhythmic contractions of the heart. (The molecular basis for this pacemaking function will be covered in [Key Concept 49.3](#).) Pacemaker cells make the vertebrate heartbeat autorhythmic, meaning it is generated by the heart muscle itself. A heart removed from a vertebrate can continue to beat with no input from the nervous system. Input from the autonomic nervous system modifies the *rate* of the pacemaker cells, but it is not essential for their continued rhythmic function.

The mechanism of excitation-contraction coupling in cardiac muscle cells is different from that in skeletal muscle cells. The T tubules are larger, and the DHP receptor proteins in the T tubules are Ca^{2+} channels. These T tubule proteins are not physically connected with the ryanodine receptors in the sarcoplasmic reticulum. Instead, when an action potential spreads down the T tubules, it causes the voltage-gated DHP channels to open, allowing extracellular Ca^{2+} to flow into the sarcoplasm. That increased sarcoplasmic Ca^{2+} binds to the ryanodine receptors and opens the calcium channels in the sarcoplasmic reticulum. The resulting huge rise in

sarcoplasmic Ca^{2+} concentration stimulates fiber contraction. This mechanism is called Ca^{2+} -induced Ca^{2+} release.

Media Clip 47.1 **Be Still My Beating Stem Cell Heart** www.Life11e.com/mc47.1

Smooth muscle causes slow contractions of many internal organs

Smooth muscle provides the contractile force for most of our internal organs, which are under the control of the autonomic nervous system. Smooth muscle moves food through the digestive tract, controls the flow of blood through blood vessels, and empties the urinary bladder. Smooth muscle also generates “goose bumps” on the skin and causes the hair on the back of a dog or cat to stand erect when the animal is being aggressive or defensive. Structurally, smooth muscle cells are the simplest muscle cells. They are smaller than skeletal muscle cells, usually long and spindle-shaped, and each has a single nucleus. They are “smooth” because the actin and myosin filaments are not as regularly arranged as they are in skeletal and cardiac muscle, and so do not produce the striated appearance.

Some smooth muscle tissue, such as that from the wall of the digestive tract, is arranged in sheets, and individual cells in a sheet are in electrical contact with one another through gap junctions, as they are in cardiac muscle. As a result, an action potential generated in one smooth muscle cell spreads to all the cells in that sheet of tissue, and the sheet contracts in a coordinated fashion.

The cell membranes of smooth muscle cells are sensitive to stretch, with important consequences. For example, if the wall of the digestive tract is stretched in one location (as by a mouthful of food passing down the esophagus to the stomach), the membranes of the stretched cells depolarize, reach threshold, and fire action potentials, which cause the cells to contract. Thus smooth muscle contracts after being stretched, and the harder it is stretched, the stronger it contracts. This behavior of smooth muscle is important for moving food through the digestive system.

The walls of blood vessels— except capillaries— are smooth muscle. This is especially true on the arterial side where the blood is under higher pressure. Changes in vascular smooth muscle tone are responsible for controlling the distribution of blood in the body.

The neural influences on smooth muscle come from the two divisions of the autonomic nervous system (see [Figure 46.8](#)). The neurotransmitters of the sympathetic and parasympathetic postganglionic cells alter the membrane potential of smooth muscle cells. For example, in the digestive tract, acetylcholine causes smooth muscle cells to depolarize, making them more likely to fire action potentials and contract. Antagonistically, norepinephrine causes these muscle cells to hyperpolarize and thus be less likely to fire action potentials and contract ([Figure 47.8B](#)). In contrast, norepinephrine acting through G protein-linked receptors causes the smooth muscle in arteries serving the gut to contract. Remember that the action of the neurotransmitters depends on the receptors in the target tissues. Sympathetic activity is high in a fight-or-flight situation; in an emergency you don't need to digest your lunch, but it could help to shunt blood to the tissues critical for survival.

(A) Overview of the experiment

(B) Experimental results

Figure 47-8 How do Autonomic Nervous System Neurotransmitters Control the Firing Rate of Smooth Muscle Cells? (A) When a strip of intestinal smooth muscle is mounted in an incubation bath so that its generation of action potentials and its force of contraction can be recorded, it is possible to test the effects of sympathetic and parasympathetic neurotransmitters on that tissue. (B) Acetylcholine depolarizes (makes less negative) the membranes and increases action potentials; norepinephrine hyperpolarizes (makes more negative) the membranes and decreases action potentials.

Smooth muscle cell contraction is not controlled by the troponin-tropomyosin mechanism, but calcium still plays a critical role. A Ca^{2+} influx into the sarcoplasm of a smooth muscle cell can be stimulated by action potentials, hormones, or stretching. The Ca^{2+} that enters the sarcoplasm combines with a protein called calmodulin. The Ca^{2+} -calmodulin complex activates an enzyme called myosin kinase that phosphorylates myosin heads. When the myosin heads in smooth muscle are phosphorylated, they undergo cycles of binding and releasing actin, causing muscle contraction. As Ca^{2+} is removed from the sarcoplasm, it dissociates from calmodulin, and the activity of myosin kinase falls. An additional enzyme, myosin phosphatase, dephosphorylates the myosin to help reduce actin-myosin interactions ([Figure 47.9](#)).

Figure 47.9 The Role of Ca^{2+} in Smooth Muscle Contraction When a smooth muscle cell is depolarized by a neurotransmitter, Ca^{2+} enters the sarcoplasm and binds to calmodulin, which in turn activates an enzyme that phosphorylates the myosin heads, causing them to bind to actin. As long as the myosin remains phosphorylated, actin and myosin go through cycles of binding and release. Thus in smooth muscle the Ca^{2+} -mediated change is on myosin, whereas in skeletal and cardiac muscle it is on the actin-tropomyosin filament.

 Animation 47.2 **Smooth Muscle Action** www.Life11e.com/a47.2

47.1 recap

The three types of muscle are skeletal, cardiac, and smooth. The contractile ability of muscle derives from interactions between actin and myosin filaments. Contraction depends on control by Ca^{2+} in the sarcoplasm. Tropomyosin and troponin are controlling elements in skeletal and cardiac muscle. Calmodulin is the controlling element in smooth muscle.

learning outcomes

You should be able to:

- Predict changes in sarcomere structure and appearance as muscle contraction occurs.
- Describe the molecular events underlying the sliding filament model of muscle contraction.
- Explain how ATP is involved in muscle contraction.
- Beginning with an action potential in a motor neuron, describe the sequence of events at the molecular level that leads to skeletal muscle contraction.
- Justify the need for gap junctions in cardiac and smooth muscle but not in skeletal muscle.

1. In terms of the arrangement of actin and myosin filaments in the sarcomere, why do the H zone and I band get smaller when the skeletal muscle contracts, and why does the A band stay the same?
2. What roles do the three subunits of troponin play in the control of skeletal muscle contraction?
3. Why does rigor mortis—the stiffening of muscles after death—occur first in muscles with the least glycogen content?
4. The insecticide Malathion destroys the enzyme acetylcholinesterase. Accidental exposure can cause extreme rigid muscle paralysis. Why?
5. Why are gap junctions important to the function of cardiac and smooth muscle, but not skeletal muscle?

Now that you understand how muscles generate force, let's look at what determines the characteristics of a muscle, its performance, and how individual muscles can change their characteristics with regular use and conditioning.

* **connect the concepts** [Key Concept 5.3](#) discussed how microfilaments made of polymerized actin are elements of the cytoskeleton that are involved in maintaining cell shape and cell movements in all eukaryotic cells.

47.2 Many Factors Affect Muscle Performance

The functions that different muscles perform place different demands on them. Some muscles, such as postural muscles, must sustain a load continuously over long periods of time. Muscles used in walking or running must vary their strength of contraction over a wide range of positions. In contrast, the jumping muscles of the frog must exert maximum force instantaneously. The muscles that control your fingers generally do not have to sustain long, strong contractions, but they must be able to undergo quick yet graded contractions for fine manual dexterity. What is “quick” for humans, however, doesn’t begin to compare with insect flight muscles that can contract as fast as 1,000 times per second. How are different muscles adapted for specific functions and demands?

focus your learning

A twitch is a unit of contraction in one muscle fiber initiated by a single action potential.

Many twitches can be summed in response to many action potentials to produce a large and/or sustained force.

Slow and fast twitch muscle fiber types differ in the rate at which they develop and maintain tension.

Three systems supply ATP to muscles for contraction, and together they determine the work capacity and endurance of a muscle.

The strength of a muscle contraction depends on how many fibers are contracting and at what rate

In skeletal muscle, the arrival of an action potential at a neuromuscular junction causes an action potential in a muscle fiber. The spread of that action potential through the muscle fiber’s T tubule system causes a minimum unit of contraction, called a **twitch**. A twitch can be measured in terms of the tension, or force, it generates (**Figure 47.10A**). A single action potential stimulates a single twitch, but the ultimate force generated by an action potential varies enormously depending on how many muscle fibers it reaches. The level of tension an entire muscle generates depends on two factors: the number of motor units activated, and the frequency at which the motor units fire.

twitch A muscle fiber’s minimum unit of contraction, stimulated by a single action potential.

Figure 47-10 Twitches and Tetanus (A) Action potentials from a motor neuron cause a muscle fiber to twitch. Twiches in quick succession can be summed. (B) Summation of many twiches can bring the muscle fiber to the maximum level of contraction, known as tetanus.

In muscles responsible for fine movements, such as those of the fingers, a motor neuron may innervate only one or a few muscle fibers, but in a muscle that produces large forces, such as the biceps, a motor neuron innervates a large number of muscle fibers.

At the level of a muscle fiber, a single action potential stimulates a single twitch. If action potentials reaching the muscle fiber are adequately separated in time, each twitch is a discrete, all-or-none phenomenon. If action potentials are fired more rapidly, however, new twiches are triggered before the myofibrils have a chance to return to their resting condition. As a result, the twiches sum, and the tension generated by the fiber increases and becomes more sustained. Thus an individual muscle fiber can show a graded response to increased levels of stimulation by its motor neuron.

Twitches sum at high levels of stimulation because the calcium pumps in the sarcoplasmic reticulum (see [Figure 47.5](#)) are unable to clear the Ca^{2+} ions from the sarcoplasm between action potentials. Eventually a stimulation frequency can be reached that results in the continuous presence of Ca^{2+} in the sarcoplasm at high enough levels to cause continuous activation of the contractile machinery—a condition known as **tetanus** ([Figure 47.10B](#)). (Do not confuse this condition with the disease tetanus, which is caused by a bacterial toxin and is characterized by spastic contractions of skeletal muscles.)

tetanus [Gk. *tetanos*: stretched] (1) A state of sustained maximal muscular contraction caused by rapidly repeated stimulation. (2) In medicine, an often fatal disease (“lockjaw”) caused by the bacterium *Clostridium tetani*.

How long a muscle fiber can maintain a tetanic contraction depends on its supply of ATP. Eventually the contracting fiber will become fatigued and be unable to sustain the contraction. It may seem paradoxical that the *lack* of ATP causes fatigue, since the action of ATP is to break actin-myosin bonds. But remember that the energy released from the hydrolysis of ATP “re-cocks” the myosin heads, allowing them to cycle through another power stroke. When a muscle

is contracting against a load, the cycle of making and breaking actin-myosin bonds must continue in order to prevent the load from stretching the muscle. The situation is like rowing a boat upstream. You cannot maintain your position relative to the stream bank by just holding the oars out against the current; you have to keep rowing. Likewise, actin-myosin bonds have to keep cycling to maintain tension in the muscle.

Many muscles of the body maintain a low level of tension even when the body is at rest. For example, the muscles of the neck, trunk, and limbs that maintain our posture against the pull of gravity are always working, even when we are standing or sitting still. Muscle tone comes from the activity of a small but changing number of motor units in a muscle; at any one time, some of the muscle's fibers are contracting and others are relaxed. The nervous system is constantly readjusting muscle tone.

Muscle fiber types determine endurance and strength

Not all skeletal muscle fibers are alike, and a single muscle often contains more than one type of fiber. The two major types of skeletal muscle fibers express different genes for their myosin molecules, and these myosin variants have different rates of ATPase activity. Those with high ATPase activity can recycle their actin-myosin cross-bridges rapidly and are therefore called [fast-twitch fibers](#); those with lower ATPase activity are called [slow-twitch fibers](#), and they develop tension more slowly but can maintain it longer ([Figure 47.11A](#)).

fast-twitch fibers Skeletal muscle fibers that can generate high tension rapidly, but fatigue rapidly ("sprinter" fibers). Characterized by an abundance of enzymes of glycolysis. (Compare to slow-twitch fibers.)

slow-twitch fibers Skeletal muscle fibers specialized for sustained aerobic work; contain myoglobin and abundant mitochondria, and are well-supplied with blood vessels. Also called oxidative or red muscle fibers. (Compare to fast-twitch fibers.)

(A) Force sustained by fast- and slow-twitch fibers

(B) Fiber type and performance

Figure 47.11 Fast- and Slow-Twitch Muscle Fibers (A) Fast-twitch fibers generate a large force quickly but fatigue rapidly. Slow-twitch fibers generate smaller forces, and do so more slowly, but can sustain them for a longer time. (B) The skeletal muscles in these three panels show slow-twitch fibers as red and fast-twitch fibers as blue. Arrows represent the duration (length) and speed (thickness) of running.

Q: What would you expect the muscle fiber distribution to be in a champion weight lifter?

Slow-twitch fibers are also called oxidative or red muscle because they contain especially large amounts of **myoglobin** (an oxygen-binding protein similar to the hemoglobin in red blood cells), have many mitochondria, and are well supplied with blood vessels. These characteristics increase the fibers' capacity for oxidative metabolism and result in their red appearance. The maximum tension a slow-twitch fiber produces is low and develops slowly but is highly resistant to fatigue. Slow-twitch fibers have substantial reserves of fuel, mostly lipids, so they can maintain steady, prolonged production of ATP as long as oxygen is available. Muscles with high proportions of slow-twitch fibers are good for long-term aerobic work (that is, work that requires oxygen). Long-distance runners, swimmers, cyclists, and other athletes whose activities require endurance have leg and arm muscles consisting mostly of slow-twitch fibers (**Figure 47.11B**).

myoglobin (my' oh globe' in) [Gk. *mys*: muscle + L. *globus*: sphere] An oxygen-binding molecule found in muscle. Consists of a heme unit and a single globin chain; carries less oxygen than hemoglobin.

Fast-twitch fibers, also called glycolytic or white muscle, have few mitochondria, little or no myoglobin, and fewer blood vessels; thus they look pale. Their major energy source is glycolysis, and therefore their major stored fuel is glycogen. Fast-twitch glycolytic fibers can develop maximum tension more rapidly than slow-twitch fibers can, and that maximum tension is greater. However, fast-twitch fibers fatigue rapidly (see [Figure 47.11A](#)). The myosin of these fibers puts the energy of ATP to work very rapidly, but the fibers cannot replenish ATP quickly enough to sustain contraction for a long time. Fast-twitch fibers are especially good for short-term work that requires maximum strength, such as sprinting (see [Figure 47.11B](#)).

The types of fibers that make up a muscle influence the performance properties of that muscle, and different muscles have different fiber compositions depending on their function. Postural muscles that maintain continuous contractions are mostly composed of slow-twitch fibers. An example is the soleus muscle that runs up the back of the leg from the heel. Its contraction extends the foot and is therefore used in walking, but its continuous contraction is required for standing. If the soleus muscle fatigued, we would fall forward. We can walk or stand for a long period of time because the soleus muscle is resistant to fatigue. In contrast, a muscle that is used mostly for short-term work, such as the biceps, has a higher percentage of fast-twitch fibers than does the soleus. We can use our biceps to pick up a heavy weight, but we cannot hold that weight in a given position for a long period of time.

Can you change the fiber composition of your muscles to optimize your performance in a particular activity? To a limited extent, you can alter the properties of your muscle fibers through training. There are fast-twitch fibers that are somewhat oxidative and therefore intermediate in their properties between slow-twitch and fast-twitch fibers. These intermediate fibers can become more oxidative with endurance training and more glycolytic with strength training. However, the most important determinant of your muscle fiber types is your genetic heritage. There is some truth to the statement that champions are born, not made. A person born with a high proportion of fast-twitch fibers in her legs is unlikely to become a champion marathon runner, and a person born with a high proportion of slow-twitch fibers in her legs is unlikely to become a champion sprinter.

A muscle has an optimal length for generating maximum tension

Two parts of a pull-up exercise are especially difficult. When your arms are fully extended, it is hard to start the pull-up; and when your chin has almost reached the bar, the last little bit is difficult. The structure of the sarcomere is the reason.

When a muscle changes length the sarcomeres also change length, and the spatial relationships between the actin and myosin filaments changes ([Figure 47.12](#)). If there is no actin-myosin overlap, cross-bridges cannot form and the sarcomere can't generate force. This is almost the situation when you are hanging from the pull-up bar. At the other extreme, when the muscle is fully contracted, the actin filaments are overlapping and the myosin filaments are bumping up against the Z lines, so additional force cannot be generated. With these considerations, you can ask how well a specific muscle—such as the frog jumping muscle—will function given a range of sarcomere lengths. In **Investigating Life: What Is the Optimal Resting Position for the Jumping Muscle of the Frog?**, we examine experiments done to identify the optimal sarcomere length for a forceful frog jump. As you review these experiments, think about how they apply to deciding on the best starting position for a sprint.

Figure 47.12 Force and Length The amount of force a sarcomere can generate depends on its resting length. When a muscle is stretched and its sarcomeres lengthened, there is less overlap between the actin and myosin filaments, and less force can be produced. When a muscle is fully contracted, the myosin filaments are bumping up against the Z lines of the sarcomeres, so further contraction is not possible.

investigatinglife What Is the Optimal Resting Position for the Jumping Muscle of the Frog?

experiment

Original Paper: Lutz, G. J. and L. C. Rome. 1994. Built for jumping: The design of the frog muscular system. *Science* 263: 370–372.

The force propelling a frog's jump should be greatest when there is optimal overlap between the actin and myosin filaments and not when the muscle is stretched. The following experiment attempted to determine the resting sarcomere length that allows a frog to achieve a maximal jump.

QUESTION ▶ If you want to get the maximum force out of a slingshot, you stretch it as far as you can. Would the frog's jump be greater if the jumping muscle were stretched when the frog was crouched before the jump?

METHOD

1. Through anatomical studies measure sarcomere length at different resting positions observed in frogs before they jump and also measure the changes in muscle length and sarcomere length during jumps.
2. Excise frog jumping muscle from a frog and mount it in a tissue culture chamber so that the muscle can be held at different lengths and electrically stimulated to contract. Attach one end of the muscle to a force transducer that measures the force generated by the contraction. With this experimental set-up you can determine the relationship between sarcomere length and maximum force the muscle can generate.
3. Compare the sarcomere length measurements with the forces measured in muscles held at different lengths.
4. Measure velocity of contraction of the muscle under different load conditions.

RESULTS

1. With methods not described here, it was determined that the jumping muscle shortened from 33.6 mm to 26.1 mm during a jump, and the resting sarcomere lengths varied from 2.34 μm to 1.82 μm .
2. The relative forces generated by isometric contraction at different sarcomere lengths corresponded well with a previously determined strength-length curve (data points shown in the graph).

CONCLUSION ▶ During the jump, the sarcomeres of the frog shortened over the optimal range for generation of force.

work with the data

The resting position of the sarcomeres and the extent of their shortening during a jump maximize the force that the frog's muscle can generate to power the jump. But in physical terms, power is a force applied over a specific time. Therefore the velocity of contraction (measured as muscle length/second [ML/s]) will influence the maximum power the muscle can generate, and the velocity of contraction depends on the load. If the load is too great, the contraction is isometric (velocity = 0). If the load is negligible, the velocity of contraction can be maximal. **Figure A** shows the relationship between force and velocity of contraction in a frog jumping muscle under different loads. The mean jump velocity is indicated. **Figure B** shows the change in muscle length (mm) during a jump (milliseconds).

Figure A

Figure B

QUESTIONS

1. Power is work/time and work is force $\times$ displacement. Displacement/time = velocity. Therefore power = force $\times$ velocity. Using the data in Figure A, plot a curve that shows power as a function of contraction velocity for the frog muscle.
2. What is the velocity of contraction of the frog jumping muscle in muscle lengths/sec? Use the data in Figure B.
3. Is the speed and force of the frog muscle optimal for generating the most powerful jump?

A similar **work with the data** exercise may be assigned in **LaunchPad**.

Exercise increases muscle strength and endurance

Different types of exercise produce different physical conditioning responses. In general, anaerobic activities such as weight lifting, increase strength, and aerobic activities such as jogging, increase endurance. Strength is the maximum force a muscle can exert, and endurance is work capacity or how long a given workload can be sustained. What are the physiological bases for these differences?

Strength is a function of the volume of the muscles: the more actin and myosin filaments in a muscle fiber, and the more muscle fibers in a muscle, the more tension it can produce. When athletes undertake strength training, they use weights or exercises such as pull-ups to repeatedly contract specific muscles under heavy loads. Repetitions are usually done until the muscle is completely fatigued. Such stress on a muscle does minor tissue damage—hence the soreness the day or two after a hard workout—but it also induces the formation of new actin and

myosin filaments in existing muscle fibers. The muscle fibers, and hence the muscles, get bigger and stronger. In extreme cases, and after serious muscle damage, new muscle fibers can also be produced from stem cells called satellite cells in the muscle. In general, however, the major effect of strength training is to produce bigger, rather than more, muscle fibers.

Aerobic exercise has a completely different effect on muscles: it enhances their oxidative capacity. This effect comes from increases in the number of mitochondria, in enzymes involved in energy use, and in the density of capillaries that deliver oxygen to the muscle. Myoglobin also increases in skeletal muscle cells. Myoglobin is similar to hemoglobin, but it has a higher affinity for oxygen. Therefore myoglobin accepts oxygen from the blood, facilitates the diffusion of oxygen throughout the muscle, and provides a store of oxygen for use when oxygen delivery by the blood is insufficient. By increasing the capacity of muscle to use oxygen to produce ATP, aerobic training increases the length of time that a given workload can be sustained.

Muscle ATP supply limits performance

Muscles have three systems for supplying the ATP they need for contraction:

- . The *immediate system* uses preformed ATP and creatine phosphate.
- . The *glycolytic system* metabolizes carbohydrates to lactate and pyruvate.
- . The *oxidative system* metabolizes carbohydrates or fats all the way to H₂O and CO₂.

The capacity of these three systems and the rates at which they can produce ATP determine both work capacity and endurance of a muscle (**Figure 47.13**).

(A) Three systems that supply ATP

(B) Timing of ATP replenishment systems

Figure 47.13 Supplying Fuel for High Performance (A) Muscles have three systems for obtaining the ATP they need for contraction during exertion such as running. (B) Looking at a plot of world-record times for running events of different durations, you can see that the performance of the athletes corresponds to the time courses of the three energy systems.

Q: [Figure 47.13B](#) shows how maximum speed decreased as the duration of the running events got longer. Explain why there are three different slopes for this curve.

ATP is present in muscles in very small amounts. However, muscle fibers also contain a storage compound called **creatine phosphate (CP)**. This molecule stores energy in a phosphate bond that it can transfer to ADP. The total energy available in all the muscles of your body in the form of ATP and CP—the immediate energy system—is only about 10 kilocalories. When at rest, you metabolize a kilocalorie of energy in less than a minute. Even though the energy available from ATP and CP is limited, it is available immediately, and it enables fast-twitch fibers to generate a lot of force quickly. During burst activity, the immediate system is exhausted in seconds.

creatine phosphate (CP) A phosphorylated creatine molecule that is abundant in skeletal muscle and can shuttle high energy phosphate from mitochondria to myofibrils.

The glycolytic system activates within a few seconds to replace the ATP depleted at the onset of muscle activity. The glycolytic enzymes are located in the cytoplasm of the muscle fiber, and therefore the ATP they generate is rapidly available to the myosin filaments. However, as noted in [Chapter 9](#), glycolysis alone is an inefficient way to produce ATP, and it leads to the accumulation of lactic acid, which slows the process. Thus the glycolytic system and the immediate system together provide the energy needed by active muscles for less than a minute (see [Figure 47.13](#)). Fortunately, oxidative metabolism becomes fully active in about a minute, producing relatively huge amounts of ATP because it can completely metabolize carbohydrates and fats to CO₂ and water. However, it requires many reactions, and it takes place in the mitochondria, so O₂ and substrate must get into the mitochondria, and the formed ATP must get from the mitochondria to the myosin filaments in the muscle. These processes are not instantaneous, so the rate at which oxidative metabolism can make ATP available to do work is slower than the rate at which the other two systems can supply ATP.

The ***fuel resources** available to the muscles influences how long someone can sustain a high level of aerobic exercise. From the circulating blood, muscle receives glucose and free fatty acids that it metabolizes to generate ATP. At high levels of aerobic exercise, however, most of the fuel used by muscles to produce ATP comes from the reserve of glycogen stored in the muscle itself. Depletion of muscle glycogen contributes to fatigue.

The rate at which muscle glycogen is replenished depends on diet. Glycogen is quickly replenished with a high-carbohydrate diet, but slowly replenished with a high-fat diet. A method used to maximize muscle glycogen is called carbo-loading. About 1 week before an athletic event, athletes typically exercise for 3-5 days at a level that depletes muscle glycogen. Then, 2-3 days before the event, they taper down their level of training and eat a diet rich in complex carbohydrates. The result can be glycogen supercompensation, in which the restoration of muscle glycogen stores “overshoots” and reaches above-normal levels.

Does Heat Cause Muscle Fatigue?

Original Paper: Grahn, D. A., V. H. Cao, C. M. Nguyen, M. T. Lieu and H. C. Heller. 2012. Work volume and strength training responses to resistive exercise improve with periodic heat extraction from the palm. *Journal of Strength and Conditioning Research* 26: 2558–2569.

Physical conditioning requires repeated intense physical activity, and the capacity of such workouts is limited by muscle fatigue. Because metabolic heat production raises the temperature of muscles during workouts, it is possible that the rise in temperature contributes to muscle fatigue and limits the capacity of workouts. To test this idea, investigators used rapid-cooling technology to extract heat from subjects during 3-minute rests between ten sets of pull-ups twice a week. In each of the ten sets of pull-ups, the subject worked until muscle failure—the inability to complete an additional pull-up. The control condition was 3-minute rests without cooling. Each subject was his own control; the subjects were randomly assigned to begin with 6 weeks of training with cooling or 6 weeks of training without cooling, followed by a reversal of the treatments. The results are shown in the figure.

QUESTIONS▶

1. What do these data indicate about the possible role of muscle temperature in muscle fatigue?
2. What do these data indicate about the relationship between workout capacity and physical conditioning effects?

Figure A

Figure B

The Effect of Cooling on Workout Capacity (A) The results for individual subjects. Open symbols indicate control treatment, closed symbols indicate cooling treatment; different colors indicate different subjects. (B) The slopes of the lines in Figure A show the rates of increase in workout capacity over the course of the experiment. Mean $\pm$ standard deviation of rate of change in pull-ups per set during the two treatment phases ($N = 6$, $P < 0.001$ paired t -tests).

Insect muscle has the greatest rate of cycling

Insect flight muscle can produce a wingbeat frequency of up to 1,000 cycles per second. Since neuronal action potentials last 1-3 milliseconds, that number of cycles per second would exceed the capacity of motor neurons, let alone the mechanism of cycling of striated muscle contraction/relaxation. The extremely fast wingbeat of a hummingbird may be only about 50 cycles per second. How do insects do it?

Vertebrate skeletal muscle and much of invertebrate skeletal muscle is called “synchronous” because the cycling of the contractile mechanism is linked to the firing of the motor neurons. Insect flight muscle does not contract in tandem with the firing of motor neurons, however, and is thus called “asynchronous” muscle. The firing of action potentials in the insect flight motor neurons is not particularly fast, but it does cause depolarization of the muscle cell membrane, the spreading of an action potential throughout the membrane, and the release of Ca^{2+} from the sarcoplasmic reticulum. However, once the asynchronous muscle fiber is stimulated, its cycle of contraction/relaxation proceeds at its own characteristic frequency as long as Ca^{2+} is available to bind to the troponin. Thus contractile cycling and the resulting wingbeat frequency are not tied to the firing rate of the flight motor neurons.

47.2 recap

Depending on the function a muscle serves, it may need to generate maximum force rapidly, sustain activity for a long period, or contract and relax at a very rapid rate. Properties of muscles can facilitate these types of activities.

learning outcomes

You should be able to:

- Explain the factors that determine how much force or tension is generated by a muscle.
 - Apply knowledge about muscle fiber types to explain how they contribute to performance abilities in aerobic versus anaerobic work.
-
1. In terms of the relationships between motor neurons and skeletal muscles, how can the nervous system control the amount of force generated by a muscle?
 2. Why do postural muscles have a higher percentage of slow-twitch fibers than do muscles used for sprinting?
 3. Apply knowledge about the three systems used by muscles as sources of ATP to explain observations about human physical performance.

Regardless of how much force a muscle can generate, how long it can sustain a workload, or how fast it can contract and relax, a muscle needs something to pull on; otherwise it would just be a lump of pulsating, quivering tissue. Let's look now at how muscle and skeletal elements work together to produce movement.

* **connect the concepts** The work performance curves for different activities reflect the complexity of the biochemical processes by which different fuel sources are metabolized to product ATP. Glycolysis supports anaerobic activities and it only entails ten enzymatic steps, so it can come on fast (see [Key Concept 9.2](#)). For aerobic activity the citric acid cycle and the

respiratory chain reactions add more steps and limit the rate of ATP production.

47.3 Muscles and Skeletal Systems Work Together

Muscles can contract and exert force, or they can relax. To create significant movement, they must have something to pull on and something that stretches the muscle back to a longer position. In some cases muscles pull on each other, as in the trunk of an elephant or the arms of an octopus. In most cases, however, [skeletal systems](#) are the rigid supports against which muscles pull to create directed movement. In this section we will examine the three types of skeletal systems: hydrostatic skeletons, exoskeletons, and endoskeletons.

skeletal systems Organ systems that provide rigid supports—**skeletons**—against which muscles can pull to create directed movements. (See *also* endoskeleton, exoskeleton.)

focus your learning

Three types of skeletons have evolved in animals, and each provides resistance against forces exerted by muscles to enable locomotion.

Three cell types, osteoblasts, osteoclasts, and osteocytes are responsible for the development and continuous remodeling of bones of vertebrates.

Bones and muscles act together across joints to form levers that produce specific types of motion.

A hydrostatic skeleton consists of fluid in a muscular cavity

Cnidarians, annelids, and other soft-bodied invertebrates have [hydrostatic skeletons](#) consisting of a volume of fluid enclosed in a body cavity surrounded by muscle (see [Key Concept 30.2](#)). When muscles oriented in one direction contract, the fluid-filled body cavity bulges out in a perpendicular direction.

hydrostatic skeleton A fluid-filled body cavity that transfers forces from one part of the body to another when acted on by surrounding muscles.

An earthworm uses its hydrostatic skeleton to crawl ([Figure 47.14](#)). The earthworm's body cavity is divided into many separate segments filled with extracellular fluid. The body wall surrounding each segment has two muscle layers: a circular layer and a longitudinal layer. If the circular muscles in a segment contract, that segment constricts and elongates. If the longitudinal muscles in a segment contract, it shortens and bulges outward. Alternating contractions of the earthworm's circular and longitudinal muscles create waves of narrowing and widening, lengthening and shortening, that travel down the body. Bulging, shortened segments serve as anchors as long, narrow segments project forward and longitudinal contractions pull other segments forward. Bristles help the widest parts of the body to hold firm against the substrate, so the body moves forward.

Figure 47.14 A Hydrostatic Skeleton Alternating waves of muscle contraction move the earthworm through the soil. The red dot enables you to follow the changes in one segment as the worm moves forward.

Exoskeletons are rigid outer structures

An **exoskeleton** is a hardened, rigid outer surface to which muscles can be attached. Contractions of the muscles cause jointed segments of the exoskeleton to move relative to each other. The simplest example of an exoskeleton is the shell of a mollusk. Some marine mollusks, such as clams, have shells composed of protein strengthened by crystals of calcium carbonate (a rock-hard material). These shells can be massive, affording significant protection against predators. Some terrestrial mollusks (and snails) generally lack the hard mineral component and are much lighter.

exoskeleton (eks' oh skel' e ton) [Gk. *exos*: outside + *skleros*: hard] A hard covering on the outside of the body to which muscles are attached. (Contrast with endoskeleton.)

The most complex exoskeletons are found among the arthropods (see [Key Concept 31.1](#)). A type of exoskeleton called a **cuticle** covers the outer surfaces of the arthropod body including its appendages. It is made up of **chitin** (a nitrogen-containing polysaccharide) secreted by a layer of cells just below the exoskeleton. Chitin stiffens and hardens the cuticle everywhere except at the joints, where flexibility must be retained. Muscles attached to the inner surfaces of the arthropod cuticle move its parts around the joints (see [Figure 31.4](#)). Growth of animals with exoskeletons is accommodated by molting (see [Figure 31.3](#)). Soft-shelled crabs, a gourmet delicacy, are crabs caught while they are molting.

cuticle (1) In plants, a waxy layer on the outer body surface that retards water loss. (2) In ecdysozoans, an outer body covering that provides protection and support and is periodically molted.

chitin (kye' tin) [Gk. *kiton*: tunic] The characteristic tough but flexible organic component of the exoskeleton of arthropods, consisting of a complex, nitrogen-containing polysaccharide. Also found in cell walls of fungi.

Vertebrate endoskeletons consist of cartilage and bone

The **endoskeleton** of vertebrates is an internal scaffolding. Muscles are attached to it and pull against it. Endoskeletons are composed of rodlike, platelike, and tubelike bones connected to one another at a variety of joints that allow a wide range of movements. An advantage of endoskeletons over the exoskeletons of arthropods is that bones in the body can grow without the animal shedding its skeleton.

endoskeleton [Gk. *endo*: within + *skleros*: hard] An internal skeleton covered by other, soft body tissues. (Contrast with exoskeleton.)

The adult human skeleton consists of 206 bones, some of which are shown in **Figure 47.15**. It can be divided into an axial skeleton, which includes the skull, vertebral column, sternum, and ribs; and an appendicular skeleton, which includes the pectoral girdle, pelvic girdle, and bones of the arms, legs, hands, and feet.

Figure 47.15 The Human Endoskeleton Cartilage and bone make up the internal skeleton of a human being.

The vertebrate endoskeleton consists of two kinds of connective tissue, cartilage and bone, which are produced by two kinds of connective tissue cells that produce extensive extracellular matrices. **Cartilage** cells produce a matrix that is a tough, rubbery mixture of polysaccharides and proteins—mainly fibrous collagen. Collagen fibers run in all directions like reinforcing cords through the gel-like matrix and give it the well-known strength and resiliency of gristle in meat. Cartilage is found in parts of the endoskeleton where both stiffness and resiliency are required, such as on the surfaces of joints where bones move against one another. Cartilage is also the supportive tissue in stiff but flexible structures such as the larynx (voice box), nose, and ear pinnae. Sharks and rays are called cartilaginous fishes because their skeletons are composed entirely of cartilage. In most other vertebrates, cartilage is the principal component of the

embryonic skeleton, but during development most of it is gradually replaced by bone.

cartilage In vertebrates, a tough connective tissue found in joints, the outer ear, and elsewhere. Forms the entire skeleton in some animal groups.

Bone also contains collagen fibers, but it gets its rigidity and hardness from an extracellular matrix of insoluble calcium phosphate crystals. Bone serves as a reservoir of calcium for the rest of the body and is in dynamic equilibrium with soluble calcium in the extracellular fluids of the body. This equilibrium is under the control of calcitonin and parathyroid hormone (see [Figure 40.13](#)). If too much calcium is taken from the skeleton, the bones are significantly weakened.

bone A rigid component of vertebrate skeletal systems that contains an extracellular matrix of insoluble calcium phosphate crystals as well as collagen fibers.

The living cells of bone—osteoblasts, osteocytes, and osteoclasts—are responsible for the constant dynamic remodeling of bone ([Figure 47.16](#)). **Osteoblasts** lay down new matrix material on bone surfaces. These cells gradually become surrounded by matrix and eventually become enclosed within the bone, at which point they cease laying down matrix but continue to exist within small lacunae (cavities) in the bone. In this state they are called **osteocytes**. Despite the vast amounts of matrix between them, osteocytes remain in contact with one another through long cellular extensions that run through tiny channels in the bone. Communication between osteocytes is important in controlling the activities of the cells that are laying down or removing bone.

Figure 47-16 Bone Is Living Tissue Bones are constantly being remodeled by osteoblasts, which lay down bone, and osteoclasts, which break down bone.

osteoblast (oss' tee oh blast) [Gk. *osteon*: bone + *blastos*: sprout] A cell that lays down the protein matrix of bone.

osteocyte (oss' tee oh site) [Gk. *osteon*: bone + *kytos*: cell] An osteoblast that has become enclosed in lacunae within the bone it has built.

The cells that break down bone and release calcium into the extracellular fluid are called **osteoclasts**. They are derived from the same cell lineage that produces white blood cells. Osteoclasts erode bone, forming cavities and tunnels. Osteoblasts follow osteoclasts, depositing new bone. Thus the interplay of osteoblasts and osteoclasts constantly replaces and remodels the bones, allowing a bone to recover from damage and adjust to the forces placed on it.

osteoclast (oss' tee oh clast) [Gk. *osteon*: bone + *klastos*: broken] A cell that dissolves bone.

A dramatic finding from the early days of manned space missions was that the bones of astronauts who spent long periods in zero gravity decalcified. Conversely, in athletes, certain bones thicken during training. Both thickening and thinning of bones are experienced by anyone who has had a leg in a cast for a long time: the bones of the uninjured leg carry the person's weight and thicken while the bones of the inactive leg in the cast thin. We now know that there are multiple mechanisms in bone that transduce physical stress into activation of various cell signaling mechanisms that can control the bone remodeling responses to those stressors.

Because of the positive effects of physical stress on bone deposition, weight-bearing exercise is effective in preventing and treating osteoporosis, which is the loss of bone density (and hence strength). More than 25 million people in the United States suffer from this debilitating condition. Although osteoporosis is most commonly a problem for postmenopausal women, it can occur in younger people as a result of malnutrition. For example, the condition known as female athlete triad includes eating disorders, cessation of menstrual cycling, and osteoporosis. These are interactive conditions in which the eating disorder and excessive training lead to malnutrition that can result in endocrine disruption and osteoporosis. Excessive training and malnutrition can lead to bone loss in males as well.

Bones develop from connective tissues

Bones are divided into two types on the basis of how they develop. **Membranous bone** forms on a scaffold of connective tissue membrane. **Cartilage bone** forms first as a cartilaginous structure resembling the future mature bone, then gradually hardens, or ossifies, to become bone. The outer bones of the skull are membranous bones; the bones of the limbs are cartilage bones.

membranous bone A type of bone that develops by forming on a scaffold of connective tissue. (Contrast with cartilage bone.)

cartilage bone A type of bone that begins its development as a cartilaginous structure resembling the future mature bone, then gradually hardens into mature bone. (Contrast with membranous bone.)

Cartilage bones can grow throughout the ossification process. The long bones of the legs and arms, for example, ossify first at the centers and later at each end (**Figure 47.17**). The cartilage between these ossification centers forms epiphyseal plates. Growth can continue until these areas of ossification join, eliminating the **epiphyseal plates**. The membranous bones forming the skull cap grow until their edges meet. The large soft spot on the top of a baby's head, called a fontanel, is a point where the skull bones have not yet joined. There are multiple fontanels in the neonate where the skull bones eventually join.

Figure 47.17 The Growth of Long Bones In the long bones of human limbs, ossification occurs first at the centers and later at each end.

epiphyseal plates Plates of cartilage near the ends of long bones where bone growth occurs up to adolescence when growth ceases.

The structure of bone may be **compact** (solid and hard) or **cancellous** (having numerous internal cavities that make it appear spongy, although it is rigid). The architecture of a specific bone depends on its position and function, but most bones have both compact and cancellous regions. The shafts of the long bones of the limbs, for example, are cylinders of compact bone surrounding central cavities that contain fatty bone marrow called yellow bone marrow. The rigid, tubelike shaft of compact bone can withstand compression and bending forces. Architects

and nature alike use hollow tubes as lightweight structural elements.

cancellous bone A type of bone with numerous internal cavities that make it appear spongy, although it is rigid. (Contrast with compact bone.)

The ends of the long bones are cancellous (see [Figure 47.17](#)). Cancellous bone is lightweight because of its numerous cavities. These cavities contain the red bone marrow responsible for red blood cell formation as well as other cellular elements of the blood. Cancellous bone is also strong because its internal meshwork constitutes a support system. It can withstand considerable forces of compression.

Most compact bone in mammals is called Haversian bone because it is composed of structural units called [Haversian systems](#) ([Figure 47.18](#)). Each Haversian system is a set of thin, concentric bony cylinders that surround a narrow canal, the Haversian canal, that contains blood vessels and nerves. Osteocytes are arranged in small spaces between the concentric circles of bone surrounding the canals. Adjacent Haversian systems are separated by boundaries called glue lines. Haversian bone is resistant to fracturing because cracks tend to stop at glue lines.

Haversian systems Units of organization in compact bone that reflect the action of intercommunicating osteoblasts.

Figure 47-18 Most Compact Bone Is Composed of Haversian Systems A micrograph of a section of a long bone shows Haversian systems with their central canals. Glue lines separate Haversian systems. Osteocytes reside in small spaces and are in communication by means of thin cell processes running through small channels.

Bones that have a common joint can work as a lever

Muscles and bones work together around **joints**, where two or more bones come together. Different kinds of joints allow motion in different directions (**Figure 47.19**), but muscles can exert force in only one direction. Therefore muscles create movement around joints by working in antagonistic pairs: when one muscle contracts, the other relaxes. When both contract, the joint becomes rigid (which is important for maintaining posture, for example).

joint In skeletal systems, a junction between two or more bones.

Figure 47.19 Types of Joint Motions The designs of joints are similar to mechanical counterparts and enable a variety of movements.

Activity 47.3 Joints www.Life11e.com/ac47.3

With respect to a particular joint, such as the knee, we refer to the muscle that bends, or flexes, the joint as the **flexor**, and the muscle that straightens, or extends, the joint as the **extensor**. The bones that meet at the joint are held together by **ligaments**, which are flexible

bands of connective tissue. Other straps of connective tissue, called **tendons**, attach the muscles to the bones. In **Figure 47.20**, which shows the knee joint, you can see a tendon that connects a flexor muscle in the upper leg (biceps femoris) to a bone in the lower leg. You can also see a tendon connecting the extensor muscle (quadriceps) to the kneecap (patella) and the patellar ligament that connects the patella to the lower leg bone. It is the patellar ligament that is tapped when testing the knee-jerk reflex (see [Figures 44.14](#)).

flexor A muscle that flexes an appendage. (Contrast with extensor.)

extensor A muscle that extends an appendage. (Contrast with flexor.)

ligament A band of connective tissue linking two bones in a joint.

tendon A collagen-containing band of tissue that connects a muscle with a bone.

Figure 47.20 Joints, Ligaments, and Tendons A side view of the knee shows the interactions of muscle, bone, cartilage, ligaments, and tendons at this crucial and vulnerable human joint.

Figure 47.21 Bones and Joints Work as Levers The three classes of levers are defined by the relationship between the fulcrum and the load and force arms. For each class of lever, the load and force arm ratio determines whether force or speed of movement is maximized.

Q: What class of lever is the knee joint?

Bones constitute a system of levers that are moved around joints by the muscles. Levers have three parts: load arm, force arm, and fulcrum. The joint is the fulcrum, and the length of the force arm relative to the load arm depends on where the muscle attaches to the bone. Three classes of levers are defined based on the location of the fulcrum (**Figure 47.21**). In a class 1 lever, the fulcrum is between the load and force arms, as in a see-saw. An example is the joint between the skull and the spinal cord. A class 2 lever is like a wheelbarrow, with the load in the middle. An example is the ankle joint and the muscle in the back of the leg that enables you to walk and stand on tiptoe. In a class 3 lever, the force arm is between the fulcrum and the load. An example is your elbow or your knee. The length ratio of the load and force arms determines whether a particular lever can exert a lot of force over a short distance or is better at translating force into large or fast movements. Think of the powerful jaws of carnivores that can easily crack bones. In contrast, the force arm of the lower legs of Rosie the Ribeter and Jackie Joyner-Kersey, featured in the opener to this chapter, is short relative to the load arm, so they can jump fast and high.

47.3 recap

Muscles can only contract and relax; to achieve organized movement, they must pull against rigid structures— other muscles, hydrostatic skeletons, exoskeletons, or endoskeletons.

learning outcomes

You should be able to:

- Describe features of hydrostatic skeletons, exoskeletons, and endoskeletons.
- Explain the functional relationships among osteoblasts, osteoclasts, and osteocytes.
- Explain the structural features of a lever of an endoskeletal system that give the lever its functional characteristics.

1. Why is molting a universal characteristic of arthropods but not of vertebrates?
2. What changes in the activities of bone cells might explain the loss of bone mass in astronauts who spend long periods at the International Space Station, and what mechanism in the bone might be responsible?
3. What is the significance of the fact that the ratio of the force arm to the load arm is much greater in the jaw joint than in the elbow joint?

QA A What adaptations optimize the jumping muscles of the frog?

Rosie the Ribeter was an exceptional jumper judged by the length of time her record remains unbeaten, but frogs in general are remarkable jumpers. This ability is not due to the molecular structure of their muscles, as the arrangement of sarcomeres is very similar across a wide cross section of animals, and in all cases, the sarcomeres and therefore the muscles only contract by about 25–30 percent of their length. So how can a muscle only a few centimeters long produce a jump of many meters? One answer, which is considered in the experiments described in *Investigating Life: What Is the Optimal Resting Position for the Jumping Muscle of the Frog?*, involves maximizing force and power. First, you saw that the resting posture of the frog maintains the sarcomere length where it can generate the maximum force when it contracts. Then by using the measured force/velocity curve, you saw that the velocity of the jump was at the level that maximized the power of the jump. This rather fast velocity of contraction is possible because the jumping muscle contains mostly fast-twitch fibers. As mentioned in the opening story, and further explained in [Key Concept 47.3](#), the legs operate as class 3 levers to move the body mass. Because the legs of the frog are long, the load arms of those levers are long in comparison with the force arms—that is, the length ratio of the load and force arms is high. A frog's long legs and big feet have another advantage as well. Muscles must have something to exert force against to maximize power, and once the frog leaves the ground, its muscles can no longer generate power. Long legs and feet ensure that as the jumping muscles contract, the feet remain in contact with the ground for a longer time, thus maximizing the power of the jump.

Future directions

Understanding how muscles and skeletal structures work together to generate movements of different types is essential in the growing field of robotics. Robots that repeat the same movement over and over are quite common in manufacturing, but more and more robotic systems are being created to do more variable and complex tasks that mimic and frequently augment the abilities of humans and other animals. For example, robots have been developed to travel over rough terrain, even while carrying heavy loads. Robots have been developed to do household chores such as washing dishes and folding laundry. Robotic systems are improving the functionality of prosthetic limbs for amputees. And melding of robotic systems with normal human functionality is leading to technologies called “exoskeletons” that greatly enhance the physical abilities of humans. The starting point in all of these engineering efforts is a thorough characterization of how the biological musculoskeletal system works.

► 47.1 Interactions of Actin and Myosin Cause Muscles to Contract

- **Skeletal muscle** consists of bundles of **muscle fibers**. Each skeletal muscle fiber is a large cell containing multiple nuclei.

skeletal muscle A type of muscle tissue characterized by multinucleated cells containing highly ordered arrangements of actin and myosin microfilaments. Also called striated muscle. (Contrast with cardiac muscle, smooth muscle.)

muscle fiber A single muscle cell. In the case of skeletal muscle, a syncytial, multinucleate cell.

- Skeletal muscles contain numerous **myofibrils**, which are bundles of **actin** and **myosin** filaments. The regular, overlapping arrangement of the actin and myosin filaments into **sarcomeres** gives skeletal muscle its striated appearance. **Review Figure 47.1, Activity 47.1**

myofibril (my' oh fy' bril) [Gk. *mys*: muscle + L. *fibrilla*: small fiber] A polymeric unit of actin or myosin in a muscle.

myosin One of the two contractile proteins of muscle. (See also actin.)

sarcomere (sark' o meer) [Gk. *sark*: flesh + *meros*: unit] The contractile unit of a skeletal muscle.

- Observations of the changes in the banding patterns of sarcomeres led to the development of **sliding filament model** of muscle contraction. **Review Figure 47.2**

sliding filament model Mechanism of muscle contraction based on the formation and breaking of crossbridges between actin and myosin filaments, causing the filaments to slide together.

- The molecular mechanism of muscle contraction involves the binding of the globular heads of myosin molecules to actin. **Review Figure 47.3, Animation 47.1**
- A single motor neuron and all the fibers it activates constitute a **motor unit**. Each nerve ending of the motor neuron forms a synapse with the muscle cell membrane. Action potentials spread across the muscle cell membrane and through the **T tubules**, causing Ca^{2+} to be released from the **sarcoplasmic reticulum**. **Review Figure 47.5, Activity 47.2**

motor unit A motor neuron and the muscle fibers it controls.

T tubules A system of tubules that runs throughout the cytoplasm of a muscle fiber, through which action potentials spread.

sarcoplasm The cytoplasm of a muscle cell.

- Ca^{2+} binds to **troponin** and changes its conformation, pulling the **tropomyosin** strands

away from the myosin-binding sites on the actin filament. The muscle fiber continues to contract until the Ca^{2+} is returned to the sarcoplasmic reticulum. **Review Focus: Key Figure 47.6**

troponin One of the three components of an actin filament; binds to actin, tropomyosin, and Ca^{2+} .

tropomyosin [troe poe my' oh sin] One of the three protein components of an actin filament; controls the interactions of actin and myosin necessary for muscle contraction.

- **Cardiac muscle** cells are striated, uninucleate, branching, and electrically connected by gap junctions, so that action potentials spread rapidly throughout sheets of cardiac muscle and cause coordinated contractions.

cardiac muscle A type of muscle tissue that makes up, and is responsible for the beating of, the heart. Characterized by branching cells with single nuclei and a striated (striped) appearance. (Contrast with smooth muscle, skeletal muscle.)

- **Smooth muscle** provides contractile force for internal organs. Smooth muscle cells respond to stretch and to neurotransmitters from the autonomic nervous system. **Review Figures 47.8, 47.9, Animation 47.2**

smooth muscle Muscle tissue consisting of sheets of mononucleated cells innervated by the autonomic nervous system. (Contrast with cardiac muscle, skeletal muscle.)

► 47.2 Many Factors Affect Muscle Performance

- In skeletal muscle, a single action potential causes a minimum unit of contraction called a **twitch**. Twitches occurring in rapid succession can be summed to achieve sustained contraction, which is known as **tetanus**. **Review Figure 47.10**

twitch A muscle fiber's minimum unit of contraction, stimulated by a single action potential.

tetanus [Gk. *tetanos*: stretched] (1) A state of sustained maximal muscular contraction caused by rapidly repeated stimulation. (2) In medicine, an often fatal disease ("lockjaw") caused by the bacterium *Clostridium tetani*.

- **Slow-twitch fibers** facilitate extended, aerobic work; **fast-twitch fibers** generate maximum forces for short periods of time. The ratio of slow-twitch to fast-twitch fibers in the muscles of an individual is largely genetically determined. **Review Figure 47.11**

slow-twitch fibers Skeletal muscle fibers specialized for sustained aerobic work; contain myoglobin and abundant mitochondria, and are well-supplied with blood vessels. Also called oxidative or red muscle fibers. (Compare to fast-twitch fibers.)

fast-twitch fibers Skeletal muscle fibers that can generate high tension rapidly, but fatigue rapidly ("sprinter" fibers). Characterized by an abundance of enzymes of glycolysis. (Compare to slow-twitch fibers.)

- The force that a muscle fiber can produce depends on its initial state of extension or

contraction. **Review Figure 47.12, Investigating Life: What Is the Optimal Resting Position for the Jumping Muscle of the Frog?**

- Anaerobic exercise stimulates the enlargement of muscle fibers through production of new microfilaments. Aerobic exercise stimulates greater oxidative capacity of muscle fibers.
- Muscle performance depends on a supply of ATP. **Review Figure 47.13**

▶ 47.3 Muscles and Skeletal Systems Work Together

- **Skeletal systems** provide supports against which muscles can pull.

skeletal systems Organ systems that provide rigid supports—**skeletons**—against which muscles can pull to create directed movements. (See also endoskeleton, exoskeleton.)

- **Hydrostatic skeletons** are fluid-filled body cavities that can be squeezed by muscles. **Review Figure 47.14**

hydrostatic skeleton A fluid-filled body cavity that transfers forces from one part of the body to another when acted on by surrounding muscles.

- **Exoskeletons** are hardened outer surfaces to which internal muscles are attached.

exoskeleton (eks' oh skel' e ton) [Gk. *exos*: outside + *skleros*: hard] A hard covering on the outside of the body to which muscles are attached. (Contrast with endoskeleton.)

- **Endoskeletons** are internal systems of rigid rodlike, platelike, and tubelike supports, consisting of **bone** and **cartilage** to which muscles are attached. **Review Figure 47.15**

endoskeleton [Gk. *endo*: within + *skleros*: hard] An internal skeleton covered by other, soft body tissues. (Contrast with exoskeleton.)

bone A rigid component of vertebrate skeletal systems that contains an extracellular matrix of insoluble calcium phosphate crystals as well as collagen fibers.

cartilage In vertebrates, a tough connective tissue found in joints, the outer ear, and elsewhere. Forms the entire skeleton in some animal groups.

- Bone is continually remodeled by **osteoblasts**, which lay down new bone, and **osteoclasts**, which erode bone. **Review Figure 47.16**

osteoblast (oss' tee oh blast) [Gk. *osteon*: bone + *blastos*: sprout] A cell that lays down the protein matrix of bone.

osteoclast (oss' tee oh clast) [Gk. *osteon*: bone + *klastos*: broken] A cell that dissolves bone.

- Bones develop from connective tissue membranes (**membranous bone**) or from cartilage (**cartilage bone**) through ossification. **Review Figure 47.17**

membranous bone A type of bone that develops by forming on a scaffold of connective tissue.

(Contrast with cartilage bone.)

cartilage bone A type of bone that begins its development as a cartilaginous structure resembling the future mature bone, then gradually hardens into mature bone. (Contrast with membranous bone.)

- Bone can be **compact** (solid and hard) or **cancellous** (containing numerous internal spaces). Most of the compact bone of mammals is composed of [Haversian systems](#). **Review Figure 47.18**

Haversian systems Units of organization in compact bone that reflect the action of intercommunicating osteoblasts.

- [Joints](#) enable muscles to power movements in different directions. Muscles and bones work together around joints as systems of levers. **Review Figures 47.19, 47.21, Activity 47.3**

joint In skeletal systems, a junction between two or more bones.

- [Tendons](#) connect muscles to bones; [ligaments](#) connect bones to one another. **Review Figure 47.20**

tendon A collagen-containing band of tissue that connects a muscle with a bone.

ligament A band of connective tissue linking two bones in a joint.

Review

2.2 Three systems supply ATP to muscles for contraction, and together they determine the work capacity and endurance of a muscle.

Original Paper: Coyle, E. F., A. R. Coggan, M. K. Hemmert and J. L. Ivy. 1986. Muscle glycogen utilization during prolonged strenuous exercise when fed carbohydrates. *Journal of Applied Physiology* 61: 165-172.

An athlete trained for endurance can sustain repeated muscle contractions far longer than someone without such training. But even trained athletes have a limit on how long they can exercise before their muscles become fatigued. One factor necessary to sustain muscle activity is the type and amount of metabolic fuel used. In this study, researchers investigated whether administering carbohydrates to athletes as they exercised would affect their time to fatigue.

Seven male, endurance-trained cyclists performed two strenuous cycling trials until they fatigued. At 20-minute intervals throughout one trial, subjects ingested a placebo (flavored water). On another day, the athletes performed the same trial, this time ingesting a glucose solution at 20-minute intervals. The researchers measured time to fatigue, muscle glycogen content in the vastus lateralis (thigh muscle), blood glucose ([Figure A](#)), carbohydrate oxidation rate ([Figure B](#)), and blood free fatty acid (FFA) concentration ([Figure C](#)). Results are shown in the table and graphs. Glycogen levels were measured in millimoles (mM) of glucosyl units per kilogram of muscle tissue. Values are means $\pm$ SE, and means are compared with a *t*-test. In the figures, significant differences are indicated with an asterisk.

Figure A

Figure B

Figure C

Treatment	Muscle glycogen at 0 hours	Muscle glycogen at 2 hours	Muscle glycogen at 3 hours	Muscle glycogen at 4 hours	Time to fatigue (hrs)
Placebo	163 ± 13	60 ± 9	37 ± 5	No data	3.02 ± 0.19
Glucose solution	173 ± 11	71 ± 11	44 ± 12	39 ± 8	4.02 ± 0.33
	<i>P</i> =0.27	<i>P</i> =0.22	<i>P</i> =0.30	<i>P</i> =0.01	

Questions

1. In these two trial groups, what were the effects of strenuous aerobic exercise on blood glucose, muscle glycogen, and carbohydrate utilization?
2. Did glucose feedings have an effect on time to fatigue? Did this effect involve maintenance of blood glucose and a slowing of muscle glycogen depletion?
3. Consider one more piece of data: comparing the muscle glycogen levels for the glucose-fed group between hour 3 and point of fatigue, the *P*-value is 0.63. What do you conclude about the effect of glucose feeding on carbohydrate metabolism in this experiment? How might the placebo group have compensated for declining carbohydrate availability?
4. Using the data on blood FFA levels in the two groups, develop an explanation for the overall effects of the glucose feeding on the energy metabolism of the subjects.
5. Suppose you have a friend training to run a marathon. Based on this study, suggest something your friend might do to improve his or her performance and ability to complete the long-distance run.

The Breath of Life

Elephant seals (*Mirounga angustirostris*) on a beach are impressive. Typical adult males are 5 meters long and weigh 2,500 kilograms. They fight viciously to defend areas of beach where the females come out of the water to give birth and rear their young. Thus the beach masters are really defending their opportunities to father the next generation.

Physiologically, these animals are even more impressive in the water. Female elephant seals, half the size of the males and therefore easier and safer to manage for experiments, have been fitted with instruments to record the depth and duration of their dives after they leave the beach where they gave birth. They spend up to 7 months at sea, and during that entire time they dive continually—day and night—to feed on eels, skates, rays, squid, and other prey. Most dives are 300-600 meters deep and last 20 minutes, but dives lasting over an hour and exceeding 2,000 meters have been recorded. The seals spend only 4-5 minutes at the surface between dives. Thus for the 80 percent of their lives that they spend at sea, they are breathing only about 20 percent of the time—12 minutes per hour!

The best human divers are perhaps the pearl divers of Japan and Korea. They typically dive repeatedly during their workday to about 20 meters, and their dives last about a minute. Record breath-hold dives for humans resting facedown in a pool are about 10 minutes, but that is a one-time event that cannot be repeated for many hours. The elephant seals are not resting—they are descending and ascending great distances and pursuing prey.

How can these behemoths spend so much time not breathing? How can they survive such crushing depths? How can they not get the bends, which is a danger for human divers? How much oxygen do these animals need to carry out their normal behavior? How much oxygen can they store in their bodies during the short times they spend at the surface? And what adaptations do they have to make those oxygen stores last as long as they do? To answer these questions, elephant seals and other diving animals have been studied in unique laboratory facilities and in the field.

What adaptations make seals champion breath-hold divers?

48.1 Respiratory Gas Exchange Is Governed by Physical Factors

The **respiratory gases** that animals must exchange are oxygen (O_2) and carbon dioxide (CO_2). Cells need to obtain O_2 from the environment to produce an adequate supply of ATP by cellular respiration (see [Chapter 9](#)). CO_2 is an end product of cellular respiration, and it must be removed from the body to prevent toxic effects. Gas exchange systems of animals consist of (1) specialized body surface areas where these gases can move between the body and the external environment, (2) mechanisms that ventilate the environmental side of those surfaces with air or water, and (3) mechanisms that circulate extracellular fluids on the internal sides.

respiratory gases Oxygen (O_2) and carbon dioxide (CO_2); the gases that an animal must exchange between its internal body fluids and the outside medium (air or water).

focus your learning

Respiratory gases diffuse from areas of higher partial pressure to areas of lower partial pressure.

Fick's law of diffusion describes the factors that determine the rate of diffusion of a gas between two locations.

Rising temperature decreases oxygen solubility in water and increases the metabolism of aquatic ectotherms.

With increasing altitude, oxygen partial pressure decreases, which decreases the rate of oxygen diffusion into the respiratory systems of animals.

Diffusion is the only means by which respiratory gases are exchanged between an animal's internal body fluids and the outside medium (air or water). There are no active transport mechanisms to move respiratory gases across biological membranes. Because diffusion is a physical process, knowing what physical factors influence rates of diffusion helps us understand the diverse adaptations of gas exchange systems. (You may want to review the coverage of diffusion in [Key Concept 6.3](#).)

Diffusion of gases is driven by partial pressure differences

Diffusion is due to the random motion of molecules, and it results in a net movement of molecules from areas of higher concentration to areas of lower concentration. In other words, diffusion evens out the distribution of molecules. Diffusion of respiratory gases occurs either in water or in air. Concentrations of gases in water or air vary with pressure because gases are compressible, a relationship described in physics by Boyle's Law. For example, there are twice as many gas molecules in a liter of gas at 2 atmospheres of pressure as there are in a liter of gas at 1 atmosphere of pressure. And if that gas is in contact with a liquid such as water, twice as many gas molecules will enter into solution when the gas pressure is 2 atmospheres than when it is 1 atmosphere.

The concentrations of different gases in a mixture are described as the **partial pressures** of those gases. To calculate the partial pressure of a gas such as oxygen in a mixture of gases

such as air, we have to know the total pressure. The total pressure of air inhaled by air-breathing animals is the atmospheric pressure. At sea level, atmospheric pressure is about 760 millimeters of mercury (mm Hg), depending on the weather. Because dry air is 20.9 percent O₂, the partial pressure of oxygen (P_{O₂}) at sea level is 20.9 percent of 760 mm Hg, or about 159 mm Hg. If two gas mixtures are separated by a membrane permeable to O₂, O₂ will diffuse from the mixture where its partial pressure is higher to the mixture where its partial pressure is lower.

partial pressures In a mixture of gasses at a specific pressure, the contribution of each gas to that total pressure.

To calculate the concentration of O₂ in the environment of a water breather, we have to know two things: the partial pressure of O₂ in the air in contact with the water, and the solubility of O₂ in water. The amount of a gas that dissolves in a liquid depends both on its partial pressure in the gas phase in contact with the liquid *and* on its solubility in that liquid. The *diffusion* of a gas between the gas phase and the liquid phase is a function of its partial pressures in those two phases; the gas diffuses from the phase with the higher partial pressure to the phase with the lower partial pressure until equilibrium is reached—the point at which the partial pressures in the two phases are equal. However, the *amount* of the gas that can be contained in the liquid depends on the solubility of that gas in that liquid. Furthermore, the solubility of a gas in a particular liquid can vary widely depending on conditions. What follows is a practical illustration of these facts.

Solubility of a gas in a liquid, such as oxygen in water, is a function of temperature—solubility is higher at low temperatures. Think of opening a bottle of warm soda in comparison to a bottle of cold soda. There is more gas out of solution—more fizz—in the warm soda. So if we have similar containers of water in equilibrium with air, but at different temperatures, the concentrations of oxygen in these water containers will be different (less O₂ in the warmer one), but the partial pressures of oxygen will be the same. Thus for water-breathing animals, the warmer the water is, the less O₂ there is per liter of water. The important point is that for a gas in solution, its concentration is not the same as its partial pressure, but partial pressures are what drive diffusion. Thus in our continuing discussions of respiratory gas exchange, we will always use partial pressure rather than concentration when referring to the diffusion of respiratory gases.

Fick's law applies to all systems of gas exchange

Whether in air or water, the diffusion rates of respiratory gases depend on their partial pressure gradients and on other factors that can be described quantitatively with a simple equation called [Fick's law of diffusion](#). All environmental variables that limit respiratory gas exchange and all adaptations that maximize respiratory gas exchange are reflected in one or more components of this equation. Fick's law is written as

Fick's law of diffusion An equation that describes the factors that determine the rate of diffusion of a molecule from an area of higher concentration to an area of lower concentration.

$$Q = DA = \frac{P_1 - P_2}{L}$$

where

Q is the rate at which a gas such as O₂ diffuses between two locations.

D is the diffusion coefficient, which is a characteristic of the diffusing substance, the medium, and the temperature. For example, perfume has a higher D than motor oil vapor, and all substances diffuse faster at higher temperatures and faster in air than in water. Temperature is not expressed explicitly in Fick's law because the diffusion coefficient is usually determined at room temperature (about 20°C).

A is the area across which the gas is diffusing.

P_1 and P_2 are the partial pressures of the gas at the two locations.

L is the path length, or distance, between the two locations.

$(P_1 - P_2)/L$ is a partial pressure gradient.

The strict dependence of animals on diffusion for gas exchange with their environments has selected for various adaptations that maximize Q , many of which we will describe in this chapter. Animals can maximize D for respiratory gases by using air rather than water as their gas exchange medium whenever possible. All other adaptations for maximizing respiratory gas exchange must influence the surface area (A) for gas exchange or the partial pressure gradient across that surface area.

Air is a better respiratory medium than water

The slow diffusion of O_2 molecules in water affects both air- and water-breathing animals. Eukaryotic cells carry out cellular respiration in their mitochondria, which are located in the cytoplasm—an aqueous medium. Cells are bathed in extracellular fluid—also an aqueous medium. In addition, all respiratory surfaces must be protected from drying out by a thin film of fluid through which O_2 must diffuse. Even in air-breathing animals, the slow rate of O_2 diffusion in water limits the efficiency of O_2 distribution from gas exchange surfaces to the sites of cellular respiration.

Diffusion of O_2 in water is so slow that even animal cells with low rates of metabolism cannot function more than a few millimeters away from a good source of environmental O_2 . Therefore there are severe size and shape limits on the many species of invertebrates that lack internal systems for distributing O_2 . Most of these species are very small, but some, such as marine flatworms, have grown larger by evolving a flat, thin body with a large external surface area ([Figure 48.1A](#)). Another strategy is seen in sponges, which have bodies made of cells that surround water channels through which the external medium flows ([Figure 48.1B](#)) (see also [Figure 30.2B](#)). A critical factor enabling larger, more complex animal bodies has been the evolution of specialized respiratory systems with large surface areas such as gills that are highly permeable to respiratory gases ([Figure 48.1C](#)).

(A) *Maia zoon orsaki*

(B) *Callyspongia plicifera*

(C) *Triturus* sp. Gills

Figure 48.1 Keeping in Touch with the Medium (A) No cell in the leaflike body of this marine flatworm is more than a millimeter away from seawater. (B) Sponges have body walls perforated by many channels, which allow water to flow between the outside world and a central cavity. No cell in the sponge is more than a millimeter away from seawater. (C) A feathery fringe of gills on this aquatic salamander provides a large surface area for gas exchange. Blood circulating through the gills comes into close contact with the respiratory medium.

O₂ can be obtained more easily from air than from water for several reasons:

The O₂ content of air is much higher than the O₂ content of an equal volume of water. The maximum O₂ content of a bubbling stream in equilibrium with air is less than 10 milliliters (mL) of O₂ per liter of water. The O₂ content of the air over the stream is about 200 mL of O₂ per liter of air.

O₂ diffuses about 8,000 times more rapidly in air than in water. That is why the O₂ content of a stagnant pond can be zero only a few millimeters below the surface.

An animal has to work (expend energy) to ventilate its gas exchange surfaces with water or air. More energy is required to move water than air because water is 800 times denser than air and about 50 times more viscous.

You can appreciate how important these facts were for the evolutionary transition of life to the terrestrial environment, because they meant that there were fewer constraints on the evolution of higher metabolic rates.

High temperatures create respiratory problems for aquatic animals

Animals that use water for their respiratory exchange medium are in a double bind when environmental temperatures rise. Most water-breathing animals are ectotherms—their body temperatures are closely tied to the temperature of the water around them. As the water temperature rises, an ectotherm's body temperature and metabolic rate rise (see [Figure 39.8](#)). Thus water breathers need more O₂ as the water gets warmer ([Figure 48.2](#)). But as mentioned above, warm water holds less dissolved gas than cold water does. In addition, since a water-breathing animal performs work to move water across its gas exchange surfaces, it must expend more energy to breathe as water temperature rises. Therefore, as water temperature goes up, a water-breathing animal must extract more and more O₂ from an environment that is

increasingly O_2 deficient, and a lower percentage of that O_2 is available to support activities other than breathing.

Figure 48.2 The Double Bind of Water Breathers Fishes need more O_2 when the water is warmer, but warm water carries less O_2 than cold water.

O_2 availability decreases with altitude

Just as a rise in water temperature reduces the supply of O_2 available to water-breathing animals, an increase in altitude reduces the O_2 supply for air breathers. At all altitudes, O_2 makes up 20.9 percent of the dry air; however, as you go up in altitude, the total amount of gas per unit of volume decreases, as reflected in the atmospheric pressure. For example, at 5,800 meters, atmospheric pressure is only half what it is at sea level, so the P_{O_2} at that altitude is only about 80 mm Hg. At the summit of Mount Everest (8,850 m), P_{O_2} is only about 50 mm Hg—roughly one-third what it is at sea level.

Because the movement of O_2 across respiratory gas exchange surfaces and into the body depends on diffusion, its rate of movement depends on the P_{O_2} difference between the air and the body fluids. Therefore the drastically reduced P_{O_2} in the air at high altitudes constrains O_2 uptake. Because of this, mountain climbers attempting peaks such as Mount Everest or K2 usually breathe O_2 from pressurized bottles.

CO_2 is lost by diffusion

Respiratory gas exchange is a two-way process: CO_2 diffuses out of the body as O_2 diffuses in. The direction and rate of diffusion of the respiratory gases across the exchange surfaces depend on the partial pressure gradients of the gases. The partial pressure gradients of O_2 and CO_2 across these exchange surfaces are quite different. The amount of CO_2 in the atmosphere is extremely low (0.03%), so for air-breathing animals there is always a large concentration gradient for diffusion of CO_2 from the body to the environment. Whereas the partial pressure gradient for O_2 decreases with increasing altitude, the gradient driving CO_2 out of the body

hardly changes. The partial pressure of carbon dioxide (P_{CO_2}) in the atmosphere is close to zero both at sea level and atop Mount Everest.

In general, getting rid of CO_2 is not a problem for water-breathing animals because CO_2 is much more soluble in water than is O_2 . Even in stagnant water, where the P_{CO_2} is higher than in moving water, the lack of O_2 becomes a problem for an animal long before CO_2 exchange difficulties arise.

48.1 recap

Respiratory gases are exchanged only by diffusion. All factors influencing respiratory gas exchanges are components of Fick's law of diffusion. Air is a better respiratory medium than water because a given volume of air has more O_2 than the same volume of water. O_2 diffuses faster in air than in water, and less work is required to move air over respiratory exchange surfaces. CO_2 exchange with the external environment occurs readily because of a large concentration gradient from the body to the environment and because CO_2 is highly soluble in water.

learning outcomes

You should be able to:

- Analyze changes in partial pressure of a gas at different altitudes and at different depths under water.
 - Apply Fick's law to explain animal adaptations that influence respiratory gas exchange.
 - Describe three factors that require a fish to increase its gill ventilation in response to an increase in its environmental temperature.
 - Explain how altitude influences respiratory gas exchange in terms of partial pressures of gases.
-
1. What is the partial pressure of oxygen in inhaled air at sea level; at 2,000 meters above sea level, where atmospheric pressure is 80 percent that of sea level; and while breathing air at the same pressure as the environment at 10 meters (= an additional 1 atmosphere of pressure) underwater?
 2. Flatworms (see [Figure 48.1A](#)) are invertebrates that do not have a respiratory system. What two components of Fick's law enable them to satisfy their need for oxygen?
 3. The O_2 content of water decreases with an increase in water temperature, but the gill ventilation rate of a fish increases much more than is necessary to match that decrease in O_2 availability. Why?
 4. In terms of Fick's law, what is the difference between the ability to exchange O_2 and CO_2 at sea level and at high altitude?

Now that we have discussed the physical factors that influence diffusion rates of respiratory gases between animals and their environments, let's look at some of the adaptations that have evolved for maximizing respiratory gas exchange.

48.2 Enhancing Diffusion Maximizes Respiratory Gas Exchange

Adaptations to maximize respiratory gas exchange are reflected in the values of Fick's law of diffusion $Q = DA (P_1 - P_2)/L$. Such adaptations have to do one or more of the following:

Increase the surface area for gas exchange (A)

Maximize the partial pressure difference driving diffusion ($P_1 - P_2$)

Minimize the diffusion path length (L)

Minimize the diffusion that takes place in an aqueous medium (maximize D)

With these factors in mind, we will look at four different respiratory systems: those of insects, fishes, birds, and mammals.

focus your learning

In insects, efficient gas exchange is facilitated by an internal network of air passages.

In fishes, countercurrent ventilation and perfusion facilitate efficient gas exchange.

In birds, anterior and posterior air sacs act as bellows to maintain a continuous unidirectional flow of air through the respiratory system.

Tidal volume, inspiratory reserve volume, and expiratory reserve volume can be measured directly, and residual volume can be determined using the helium dilution method.

Respiratory organs have large surface areas

A variety of anatomical adaptations maximize the specialized body surface areas (A) for respiratory gas exchange. Water-breathing animals generally have gills, and air-breathing animals have tracheae or lungs. Gills are highly branched and folded extensions of the body surface that provide a large surface area for gas exchange ([Figure 48.3A](#)); see also [Figure 48.1 C](#)). Because gills consist of thin, delicate tissues, they minimize the path length (L) traversed by diffusing molecules of O_2 and CO_2 . [External gills](#) are found in larval amphibians and in the larvae of many insects. External gills are vulnerable to damage and are tempting morsels for predators, so in many animals protective body cavities for gills have evolved. Such [internal gills](#) are found in most mollusks and arthropods and in all fishes ([Figure 48.3B](#)).

Figure 48.3 Gas Exchange Systems Large surface areas (tan in these diagrams) for the diffusion of respiratory gases are common features of animals. External **(A)** and internal **(B)** gills are adaptations for gas exchange with water. Lungs **(C)** and tracheae **(D)** are organs for gas exchange with air.

external gills Highly branched and folded extensions of the body surface that provide a large surface area for gas exchange with water; typical of larval amphibians and many larval insects.

internal gills Gills enclosed in protective body cavities; typical of mollusks, arthropods, and fishes.

Lungs are internal cavities for respiratory gas exchange with air (**Figure 48.3C**). Their structure is quite different from that of gills. Lungs have a large surface area because they are highly divided, and because they are elastic, they can be inflated with air and deflated.

lung An internal organ specialized for respiratory gas exchange with air.

Insects have a respiratory gas exchange system consisting of a network of air-filled tubes called **tracheae** that branch through all tissues of the insect's body (**Figure 48.3D**). The terminal branches of these tubes are so numerous that they have an enormous surface area compared with the external surface area of the insect's body.

trachea (tray' kee ah) [Gk. *trakhoia*: tube] A tube that carries air to the bronchi of the lungs of vertebrates. When plural (**tracheae**), refers to the major airways of insects.

Ventilation and perfusion of gas exchange surfaces maximize partial pressure gradients

Partial pressure gradients $[(P_1 - P_2)/L]$ drive diffusion across gas exchange surfaces; the larger the gradient, the greater the rate of gas exchange. These gradients can be maximized in several ways:

Minimizing path length: Very thin tissues in gills and lungs reduce the diffusion path length (L).

Ventilating: Actively moving the external medium over the gas exchange surfaces (i.e., breathing) regularly exposes those surfaces to fresh respiratory medium containing maximum

O₂ and minimum CO₂ concentrations. This maximizes the partial pressure gradients.

Perfusing: Actively moving the internal medium (e.g., blood) over the internal side of the exchange surfaces transports CO₂ to those surfaces and O₂ away from them, thus maximizing the partial pressure gradients driving diffusion.

Insects have airways throughout their bodies

The tracheal system that enables insects to exchange respiratory gases extends to all tissues in the insect body. Thus respiratory gases diffuse through air most of the way to and from every cell. The insect respiratory system communicates with the outside environment through gated openings called spiracles in the sides of the abdomen and thorax (**Figure 48.4A**) and **B**). The spiracles open to allow gas exchange and then close to decrease water loss. They open into tubes called tracheae that branch into even finer tubes, or tracheoles, that end in tiny air capillaries—the actual gas exchange surfaces (**Figure 48.4C**).

Figure 48.4 The Tracheal Gas Exchange System of Insects(A) In insects, respiratory gases diffuse through a system of air sacs and tubes (tracheae) that open to the external environment through holes called spiracles. (B) The spiracles of a hawkmoth larva run down its sides. (C) A scanning electron micrograph shows an insect trachea dividing into smaller tracheoles and still finer air capillaries.

Fish gills use countercurrent flow to maximize gas exchange

The internal gills of fish are supported by gill arches that lie between the mouth cavity and the protective opercular flaps on the sides of the fish just behind the eyes (**Figure 48.5A**). Water flows unidirectionally into the fish's mouth, over the gills, and out from under the opercular flaps. Thus there is a constant one-way flow of oxygenated water over the gills, maximizing the PO₂ on the external gill surfaces. On the internal side of the gill membranes, the circulation of blood minimizes the P_{O₂} by sweeping O₂ away as rapidly as it diffuses across.

Figure 48.5 Fish Gills (A) Water flows unidirectionally over the gills of a fish, in through the mouth and out through the opercular opening. (B) Gill filaments have a large surface area and thin tissues. (C) Gill filaments are lined with lamellae, which

are the gas exchange surfaces. Blood flows through the lamellae countercurrent (left to right in this drawing; small blue and red arrows) to the direction of the flow of water across the gills (right to left in this drawing; large blue arrows).

Gills have an enormous surface area for gas exchange because they are so highly subdivided. Each gill consists of hundreds of ribbonlike gill filaments (**Figure 48.5B**). The upper and lower flat surfaces of each gill filament are covered with rows of evenly spaced folds, or lamellae (**Figure 48.5C**). The lamellae are the actual gas exchange surfaces. Because the lamellae are exceedingly thin, the path length (L) for diffusion of gases between blood and water is minimized. The surfaces of the lamellae consist of highly flattened epithelial cells, so the water and the fish's red blood cells are separated by little more than 1-2 micrometers.

The flow of blood perfusing the inner surfaces of the lamellae, like the flow of water over the gills, is unidirectional. **Afferent** blood vessels bring deoxygenated blood to the gills, while **efferent** blood vessels take oxygenated blood away from the gills (see **Figure 48.5C**). Blood flows through the lamellae in the direction opposite to the flow of water over the lamellae. This **countercurrent flow** optimizes the P_{O_2} gradient between water and blood, making gas exchange more efficient than it would be in a system using concurrent (parallel) flow (**Figure 48.6**).

afferent (af' ur unt) [L. *ad*: toward + *ferre*: to carry] Carrying to, as in neurons that carry impulses to the central nervous system (**afferent neurons**), or a blood vessel that carries blood to a structure (**afferent arterioles**). (Contrast with efferent.)

efferent (ef' ur unt) [L. *ex*: out + *ferre*: to bear] Carrying outward or away from, as in neurons that carry impulses outward from the central to the peripheral nervous system (**efferent neurons**), or a blood vessel that carries blood away from a structure (**efferent arterioles**). (Contrast with afferent.)

countercurrent flow An arrangement that promotes the maximum exchange of heat, or of a diffusible substance, between two fluids by having the fluids flow in opposite directions through parallel vessels close together.

Figure 48.6 Countercurrent Flow Enables More Complete Exchange In these models of concurrent and countercurrent gas exchange, the numbers represent the

O₂ saturation percentages of blood and water. **(A)** In a concurrent exchanger, the saturation percentages of blood and water reach equilibrium halfway across the exchange surface. **(B)** A countercurrent exchanger allows more complete gas exchange because the water always has a higher PO₂ than the blood; thus a gradient of PO₂ supports diffusion of O₂ into the blood across the entire length of the exchanger.

Q: What could make the concurrent exchanger achieve the same maximum O₂ saturation as the countercurrent exchanger?

Some fishes, including anchovies, tuna, and certain sharks, ventilate their gills by swimming almost constantly with their mouths open. Most fishes, however, ventilate their gills by means of a two-pump mechanism. The closing and contracting of the mouth cavity pushes water over the gills, and the expansion of the opercular cavity prior to opening of the opercular flaps pulls water over the gills.

These adaptations for maximizing the surface area (*A*) for diffusion, minimizing the path length (*L*) for diffusion, and maximizing the P_{O₂} gradient allow fishes to extract an adequate supply of O₂ from meager environmental sources.

Birds use unidirectional ventilation to maximize gas exchange

Birds are remarkable for their ability to sustain high levels of activity for a long time—for example, on long-distance flights—even at high altitudes where mammals cannot even survive. The first team to climb Mount Everest (8,850 meters) was surprised to see birds flying over the mountain when they themselves could barely move without supplemental O₂. Bar-headed geese regularly migrate over Mount Everest and surrounding peaks, but the highest recorded flight of a bird is from a Ruppell's griffon, a vulture, that was sucked into a jet engine at 11,278 meters. Humans cannot survive at such altitudes without supplemental O₂. Yet the lungs of a bird are smaller than the lungs of a similar-sized mammal, and bird lungs expand and contract less during a breathing cycle than do mammalian lungs. And the volume of bird lungs decreases during inhalation and increases during exhalation. How do birds accomplish such remarkable feats of respiratory gas exchange?

The structure of bird lungs allows air to flow unidirectionally through the lungs, rather than bidirectionally through all the same airways, as it does in tidally ventilating mammals (discussed below). Because mammalian lungs are never completely emptied of air during exhalation, there is always some lung volume that is not ventilated with fresh air. The air remaining in lungs and airways after exhalation is called **dead space**. Bird lungs, by contrast, have very little dead space, and the fresh incoming air is not mixed with stale air. In this way, a high PO₂ gradient is maintained.

dead space The lung volume that fails to be ventilated with fresh air (because the lungs are never completely emptied during exhalation).

Air sacs are an important and unique feature of the avian respiratory system, and they occupy much of the body cavity of the bird (**Figure 48.7A**). They can be divided into a group of anterior air sacs and a group of posterior air sacs. The air sacs are interconnected with each other, with the lungs, and with air spaces in some of the bones. The air sacs are not gas exchange surfaces; rather, they act as bellows to maintain a unidirectional flow of air through the lungs.

air sacs Structures in the respiratory system of birds that receive inhaled air; they keep fresh air flowing unidirectionally through the lungs, but are not themselves gas exchange surfaces.

(A) Avian air sacs and lungs

(B) Diagram of respiratory system

(C) Microscopic view of avian lung tissue

Air capillaries are located between the parabronchi and are in close contact with blood capillaries. O_2 from the large surface area of the air capillaries diffuses into the blood capillaries.

Figure 48.7 The Respiratory System of a Bird (A) Air sacs in the body cavity and air spaces in the bones are unique to birds. (B) Air comes in through the trachea, which divides into a left and a right primary bronchus. The primary bronchi go to the

posterior air sacs. Secondary bronchi connect the posterior air sacs to the lungs. Air flows unidirectionally through the lungs in numerous parabronchi and flows in bronchi from the lungs to the anterior air sacs, then out through the trachea. **(C)** Air capillaries running between the parabronchi are the site of gas exchange.

As in other air-breathing vertebrates, air enters and leaves a bird's gas exchange system through the **trachea** (commonly known as the windpipe, and not to be confused with the air-conducting tracheae of insects) (**Figure 48.7B**). The trachea divides into two smaller airways, the **primary bronchi** (singular *bronchus*). The primary bronchi extend all the way to the posterior air sacs and also branch into **secondary bronchi**. The posterior air sacs also have connections to the secondary bronchi. Secondary bronchi divide into tubelike **parabronchi** that run parallel to one another through the lungs.

trachea (tray' kee ah) [Gk. *trakhoia*: tube] A tube that carries air to the bronchi of the lungs of vertebrates. When plural (**tracheae**), refers to the major airways of insects.

primary bronchi The first airways that branch off of the trachea.

secondary bronchi The airways branching off of the primary bronchi.

parabronchi Passages in the lungs of birds through which air flows.

Branching off the parabronchi are numerous tiny air capillaries (**Figure 48.7C**). Air flows through the parabronchi and diffuses into the air capillaries, which are the gas exchange surfaces. The air capillaries are so numerous that they provide an enormous surface area for gas exchange. The blood capillaries are in close contact with the air capillaries, and oxygen from the air diffuses into the blood. The parabronchi coalesce into larger bronchi that take the air out of the lungs and into anterior air sacs and then back to the trachea. Thus the anatomy of a bird's airways allows air to flow unidirectionally through the lungs: trachea, bronchi, posterior air sacs, parabronchi, bronchi, anterior air sacs, trachea.

The puzzle of how birds breathe was solved by placing small O₂ sensors at different locations in birds' air sacs and airways. The birds were then allowed to inhale pure O₂ for just a single breath, which made it possible to track that particular breath by recording when each of the O₂ sensors registered a peak value. The experiment showed that a single breath remains in a bird's respiratory system for two cycles of inhalation and exhalation. During inhalation, the air sacs expand and air flows through the trachea into the posterior air sacs. At the same time, the lungs are contracting as air moves from the lungs into the anterior air sacs. During exhalation, the air sacs contract. The posterior air sacs push air into the lungs, which are expanding, and the anterior air sacs push air into the trachea and out of the respiratory system. This bellowslike action of the air sacs maintains a continuous, unidirectional flow of fresh air through the lungs (**Figure 48.8**).

Breath 1

- 1 A single inhaled breath of pure O_2 flows directly to the posterior air sacs.

- 2 During the following exhalation, the marked breath flows into the lungs.

Breath 2

- 3 During the next inhalation, the marked breath flows from the lungs to the anterior air sacs.

- 4 Finally, during the second exhalation, the breath marked by pure O_2 is expelled.

Figure 48.8 An Experiment to Describe Airflow in Bird Respiratory System

Oxygen sensors placed in different locations in the bird respiratory system trace the flow of a single breath of pure oxygen (blue) through the system. A single breath remains in the system for two breathing cycles.

The advantages of the bird respiratory system are similar to those of fish gills. The air sacs keep fresh air flowing unidirectionally over the gas exchange surfaces without interruption. Thus those gas exchange surfaces are constantly exposed to a P_{O_2} that is very close to that of the ambient air. Even at high altitude where the P_{O_2} of the ambient air may be only slightly above that of the blood, O_2 can still diffuse from air to blood.

Tidal ventilation produces dead space that limits gas exchange efficiency

Lungs evolved in early lungfishes as outpocketings of the digestive tract. Although lung structure has evolved considerably, lungs remain dead-end sacs in all air-breathing vertebrates except birds (and likely their extinct reptilian ancestors). Ventilation of dead-end sacs with common passageways for inflow and outflow cannot be constant and unidirectional but must be **tidal**: air flows in and exhaled gases flow out by the same route. Since the lungs and airways can never be completely emptied of air, they always contain dead space. We can easily measure the volumes of air exchanged during breathing, but we have to use an indirect method to measure the dead space contained in the lungs and airways. Measures of dead space are important in assessing lung health and disease.

tidal The bidirectional form of ventilation used by all vertebrates except birds; air enters and leaves the lungs by the same route.

A flowmeter measures the volume of air breathed in and out (**Figure 48.9**). Using a human as an example, the amount of air that moves either in or out per breath when at rest is called the **tidal volume (TV)** (about 500 mL for an average human adult). When we breathe in as much as possible, the additional volume is the **inspiratory reserve volume (IRV)**. Conversely, if we forcefully exhale as much air as possible, the additional amount of air expelled is the **expiratory reserve volume (ERV)**. The maximum capacity for air exchange in one breath, or the **vital capacity (VC)**, is the sum of $TV + IRV + ERV$. The vital capacity of an athlete is generally greater than that of a nonathlete, and vital capacity decreases with age because of stiffening of the lung tissue.

Figure 48.9A Measuring Lung Ventilation A flowmeter is a device that measures the volume of air a person breathes through a mouthpiece. The combined tidal volume, inspiratory reserve volume, and expiratory reserve volume are the lungs' vital capacity. The vital capacity plus the residual volume are the total lung capacity.

work with the data

Figure 48.9B Measuring Lung Ventilation

A patient complains of always being short of breath. Using a flowmeter, the physician determines that the patient's tidal volume is 0.3 L and his expiratory reserve volume is 1.5 L. The physician decides to use the Fick dilution method to measure the patient's residual volume. She attaches the flowmeter to a 30-liter air reservoir containing 5% helium. Using a two-way valve, she can have the patient breathe room air or the air in the reservoir. At the end of a tidal exhalation, the physician turns the valve and lets the patient take 10 breaths from the reservoir. She then switches the patient to room air at the end of a tidal exhalation. She determines that the volume of the reservoir is still 30 L, but the helium concentration in the reservoir is now 4.4%.

QUESTIONS ►

1. What is the patient's residual volume?
2. Why do you think the patient complains of always being short of breath?

A similar **work with the data** exercise may be assigned in **LaunchPad**.

tidal volume (TV) The volume of air inhaled and exhaled by a resting individual. (Contrast with expiratory reserve volume, tidal volume, vital capacity.)

inspiratory reserve volume (IRV) The amount of air that can be inhaled above the normal tidal inspiration. (Contrast with expiratory reserve volume, tidal volume, vital capacity.)

expiratory reserve volume (ERV) The amount of air that can be forcefully exhaled beyond the normal tidal expiration. (Contrast with inspiratory reserve volume, tidal volume, vital capacity.)

vital capacity (VC) The maximum capacity for air exchange in one breath; the sum of the tidal volume and the inspiratory and expiratory reserve volumes.

Vital capacity is not the entire lung capacity because of the dead space, also called the **residual volume (RV)**. We can't measure RV directly with the flowmeter, but we can measure it indirectly using the helium dilution method. The flowmeter is attached to a closed reservoir of air of a known volume (V_{res}) so that a person can breathe in and out from that reservoir. If this reservoir has a known amount of helium (He) in it, and a subject breathes the air in that reservoir through several breathing cycles, the helium will become distributed in the reservoir and in the subject's respiratory system. Helium is not absorbed into the body from the lungs, so the total amount of helium at the beginning of a test (He_i) will equal the total amount at the end of the test (He_f)—it will just be distributed over a larger volume and therefore be less concentrated. The following formula quantifies that relationship:

residual volume (RV) In tidal ventilation, the dead space that remains in the lungs at the end of exhalation.

Initial amount of He = final amount of He

We start the subject breathing from the reservoir at an end-tidal breath, and we end the breathing from the reservoir at an end-tidal breath. Since the V_{res} does not change, the decrease in helium concentration $[\text{He}]$ enables us to calculate the subject's **functional residual volume (FRV)**, which is the ERV + RV.

functional residual volume (FRV) The residual volume plus the expiratory reserve volume.

$$V_{\text{res}} \times [\text{He}]_i = (V_{\text{res}} + \text{FRV}) \times [\text{He}]_f$$

Since we can measure the ERV with the flowmeter, we can subtract the ERV from the FRV to obtain the RV.

Why is the RV important? Referring to [Figure 48.9](#), you will see that for a normal person the ERV is about 1,000 mL and the RV is 1,000 mL. Thus the FRV is 2,000 mL, but the tidal volume is only 500 mL; this means that the air that reaches the alveoli (the actual gas exchange surfaces) with each breath consists of only 500 mL of fresh air diluted by 2,000 mL of stale air. The maximum P_{O_2} in this mixed air is much below the P_{O_2} of the outside air, and because of the tidal ventilation pattern, the P_{O_2} in the alveoli is steadily dropping during the breathing cycle. The RV is important because it contributes to the FRV and to the dilution of the O_2 in the inhaled air. Any disease or condition that increases the RV (such as emphysema or pulmonary fibrosis) compromises a patient's respiratory ability. Similarly, considering the mixing of fresh air with the FRV, you can understand why reductions in tidal volume can be a problem—and therefore why patients recovering from surgery are encouraged to breathe deeply, even if it hurts.

Small residual volume prevents the bends in seals

In the opening of this chapter we discussed the remarkable abilities of elephant seals to dive to great depths for long times and then spend only minutes breathing at the surface. We asked how elephant seals avoid getting the bends, a very painful condition that develops in scuba divers who surface too rapidly after spending time at depths. The pressure of the water on the body increases by 1 atmosphere for every 10 meters of depth. Body tissues are not compressible, but air in the respiratory system is, so scuba divers breathe air through a regulator that equalizes the air pressure in their lungs to the pressure of the water on the body. As the total air pressure goes up, the partial pressures of the component gases go up, increasing their rate of diffusion into the tissues. Eighty percent of the air is nitrogen, so the amount of nitrogen dissolved in tissues increases. If the diver comes up too rapidly, the dissolved nitrogen comes out of solution in the tissues, creating small bubbles that block blood vessels, damage tissues, cause pain, and can even result in death. To avoid the bends, divers use decompression tables that tell them how to ascend depending on how deep and how long their dives have been. For example, if a diver has spent 1 hour at a depth of 60 meters, he would have to spend 3 hours gradually ascending to shallower and shallower depths to allow the nitrogen dissolved in his tissues to diffuse out through the respiratory system rather than form bubbles in his tissues. Why does a seal who makes repeated dives not face the same consequences? The seal exhales before diving and the residual air in its respiratory system gets compressed into its airways, which are not respiratory exchange surfaces. So, when seals dive they do not have compressible air in their lungs that can be forced into tissues at depth and then

come out of solution upon resurfacing.

48.2 recap

The major adaptations that increase efficiency of respiratory gas exchange are large surface areas for exchange and maximized partial pressure gradients across those surfaces. Fish and avian respiratory systems have continuous and unidirectional ventilation of their respiratory exchange surfaces. Mammals have tidal ventilation, resulting in residual volumes of O_2 that dilute the incoming fresh air.

learning outcomes

You should be able to:

- Explain the concept and adaptive significance of countercurrent exchange, using the fish gills as the example.
- Describe how the avian respiratory system maximizes the partial pressure gradient for O_2 uptake.
- Determine the total lung capacity (including residual volume) of a human.

1. Given constant rates of ventilation and perfusion, how can the directionality of blood and water flow on opposite sides of fish gill membranes influence the maximum O_2 exchange that can occur?
2. How do birds maintain a constant and unidirectional flow of air through their lungs?
3. Find the functional residual volume of a person who yields the following data while breathing from a flowmeter that has a volume of 30 liters (L) and an initial gas mixture of 20 percent O_2 , 75 percent nitrogen (N), and 5 percent helium (He). Beginning with an inhalation, the person inhales and exhales 20 times. The final concentration of He in the flowmeter is 4.6 percent.

Despite their limitations, mammalian lungs serve the respiratory needs of mammals well. Offsetting the inefficiencies of tidal breathing, mammalian lungs have an enormous surface area and a very short path length for diffusion. Next we will look at the human respiratory system as an example.

48.3 Humans Have Tidal Respiration

The respiratory exchange surfaces in mammalian lungs are the very thin-walled alveoli that cluster around a huge number of finely branching terminal airways. To understand how these respiratory surfaces are ventilated and perfused, we will first examine the functional anatomy of the whole respiratory system (**Focus: Key Figure 48.10**).

focus: key figure

(A) Respiratory system

Figure 48.10 The Human Respiratory System The diagrams trace the hierarchy of human respiratory structures, from the airways to the minuscule alveoli.

Q: If the trachea branches into two bronchi, each of those bronchi branches into two smaller airways, and so forth for 23 branchings, how many terminal airways are there?

Activity 48.1 The Human Respiratory System www.Life11e.com/ac48.1

Mucus traps particulates in the inhaled air and surfactants decrease the work of ventilation.

Inhalation and exhalation of air result from changes in the volume and the pressure in the thoracic cavity.

Lungs are ventilated through a branching system of airways

Air enters the lungs through the oral cavity or through the nasal passages, which join together in the **pharynx** (see [Figure 48.10A](#)). Below the pharynx, the esophagus conducts food to the stomach, and the trachea conducts air to the lungs. At the beginning of this airway is the **larynx**, or voice box, which houses the vocal cords. The larynx is the lump that you can see or feel on the front of your neck. The trachea is about 2 centimeters in diameter. C-shaped bands of cartilage prevent the thin walls of the trachea from collapsing as air pressure changes during the breathing cycle. If you run your fingers down the front of your neck just below your larynx, you can feel a few of these bands of cartilage.

pharynx [Gk. throat] The part of the gut between the mouth and the esophagus.

larynx A structure between the pharynx and trachea that contains the vocal cords.

The trachea branches into two **bronchi**, one leading to each lung. The bronchi branch repeatedly to generate a treelike structure of progressively smaller airways extending to all regions of the lungs. After four branchings, the cartilage supports disappear, marking the transition to **bronchioles**. After about 16 branchings, the bronchioles are less than a millimeter in diameter, and tiny, thin-walled air sacs called **alveoli** begin to appear. Alveoli are the sites of gas exchange. After the first alveoli there are about six more branchings of the airways that end in clusters of alveoli (see [Figure 48.10B](#)). Because the airways conduct air only to and from the alveoli and do not themselves participate in gas exchange, their volume is dead space.

bronchus (plural: bronchi) The major airway(s) branching off the trachea into the vertebrate lung.

bronchioles The smallest airways in a vertebrate lung, branching off the bronchi.

Human lungs have about 300 million alveoli. Although each alveolus is very small, their combined surface area for diffusion of respiratory gases is about 70 square meters—about one-fourth the size of a basketball court. The walls of each alveolus are made of very thin cells. Wrapped around the alveoli are networks of capillaries that also have very thin walls. Thus where capillary meets alveolus, the diffusion path length between air and blood is less than 2 micrometers (see [Figure 48.10C](#)).

Diseases of the bronchioles and alveoli are the third leading cause of death in the United States as of 2014. Among these diseases, the most lethal is emphysema, a condition in which inflammation damages and eventually destroys the walls of the alveoli. As a result, the lungs have fewer but larger alveoli, the lungs lose elasticity, and the RV increases. The principal cause of emphysema is smoking.

Respiratory tract secretions aid ventilation

Mammalian lungs produce two secretions that do not directly influence their gas exchange but do affect the process of ventilation: mucus and surfactant.

Many cells lining the airways produce sticky mucus that captures bits of dirt and microorganisms that are inhaled. Other cells lining the airways have cilia that beat continually

and sweep the mucus, with its trapped debris, up toward the pharynx, where it is swallowed or spit out. This phenomenon, called the mucus escalator, can be adversely affected by inhaled pollutants. Smoking one cigarette can immobilize the cilia of the airways for hours. A smoker's cough results from the need to clear the obstructing mucus from the airways when the mucus escalator is out of order.

A **surfactant** is a substance that reduces the surface tension of a liquid. **Surface tension** gives the surface of a liquid the properties of an elastic membrane, and it is why certain insects, such as water-striders, can walk on water. As discussed in [Key Concept 2.4](#), surface tension is the result of chemical forces of attraction between water molecules. The attractive forces working on the water molecules at the surface pull from below and from the sides but not from above. This imbalance of forces creates surface tension. The thin film of fluid covering the air-facing surfaces of the alveoli has surface tension that contributes to the lungs' elasticity. To inflate the lungs, enough force has to be generated to overcome both the elasticity of the lung tissue and the surface tension in the alveoli.

surfactant A substance that decreases the surface tension of a liquid. Lung surfactant, secreted by cells of the alveoli, is mostly phospholipid and decreases the amount of work necessary to inflate the lungs.

surface tension The attractive intermolecular forces at the surface of liquid; an especially important property of water.

Lung surfactant is a fatty, detergent-like substance that is critical for reducing the work necessary to inflate the lungs. Certain cells in the alveoli release surfactant molecules. If a baby is born more than a month prematurely, these cells may not have developed the ability to produce surfactant. A baby with this condition, known as respiratory distress syndrome, will have great difficulty breathing and may die from exhaustion and lack of O₂. Common treatments for premature babies have been to put them on respirators to assist their breathing and to give them hormones to speed lung development. A newer approach is to apply surfactant to the lungs via an aerosol.

Lungs are ventilated by pressure changes in the thoracic cavity

Human lungs are suspended in the **thoracic cavity**, a closed compartment bounded on the bottom by a sheet of muscle called the **diaphragm** (see [Figure 48.10A](#)). Each lung is covered by a continuous sheet of tissue called the **pleural membrane** that also lines the thoracic cavity adjacent to the lung. A thin film of fluid between the pleural membranes of the lung and the thoracic cavity lubricates the inner surfaces of the pleural membranes so they can slip and slide against each other. As with surface tension, there are forces of attraction between the molecules of fluid covering the pleural membranes. As a result, it is difficult to pull the pleural membranes apart. Think of two wet panes of glass or two wet microscope slides; you can slide them past each other, but it is difficult to separate them. While the inner surfaces of the pleural membranes are "stuck" to each other by surface tension, they can move relative to each other during breathing movements.

thoracic cavity [Gk. *thorax*: breastplate] The portion of the mammalian body cavity bounded by the ribs, shoulders, and diaphragm. Contains the heart and the lungs.

diaphragm (dye' uh fram) [Gk. *diaphrassein*: barricade] (1) A sheet of muscle that separates the thoracic and abdominal cavities in mammals; responsible for breathing. (2) A method of birth control in which a sheet of rubber is fitted over the woman's cervix, blocking

the entry of sperm.

pleural membrane [Gk. *pleuras*: rib, side] The membrane lining the outside of the lungs and the walls of the thoracic cavity. Inflammation of these membranes is a condition known as pleurisy.

Inhalation and exhalation involve changes in the volume of the thoracic cavity (**Figure 48.11**). Because the pleural membranes covering the cavity wall and the lung surface are stuck to each other by surface tension, any attempt to increase the volume of the thoracic cavity increases the tension between the pleural membranes. Even between breaths, there is tension between the pleural membranes because the rib cage is pulling outward and the elasticity of the lung tissue is pulling inward. This slight negative pressure keeps the alveoli partly inflated even at the end of an exhalation. If the thoracic cavity is punctured—by a knife wound, for example—air can leak into the space between the pleural membranes and cause the lung to deflate. If the wound is not sealed, breathing movements pull air in between the pleural membranes rather than into the lung (a “sucking chest wound”), and there is no ventilation of the alveoli in that lung—a condition called “collapsed lung.”

Figure 48.11 Into the Lungs and Out Again (A) Inhalation is an active process spurred by contraction of the diaphragm. (B) Exhalation generally is a passive process as the diaphragm relaxes. (C) Strong inhalations and exhalations also involve the external and internal intercostal muscles. (D) Between breaths, the intra-alveolar pressure is the same as the external barometric pressure, but the interpleural pressure is still negative and keeps the lungs from collapsing. During inhalation the interpleural pressure becomes more negative, expanding the lungs and causing the intra-alveolar pressure to become negative, which pulls air into the lungs.

 Animation 48.2 Airflow in Mammals www.Life11e.com/a48.2

At rest, inhalation is initiated by contraction of the muscular diaphragm (see **Figure 48.11A**). As the domed diaphragm contracts, it pulls down, expanding the thoracic cavity and pulling on

the pleural membranes. Since the pleural membranes cannot separate, they pull on the lungs increasing their volume, and air rushes in through the trachea from the outside. Exhalation begins when contraction of the diaphragm ceases. As the diaphragm relaxes, the elastic recoil of the lung tissues pulls the diaphragm up and pushes air out through the airways (see [Figure 48.11B](#)). When a person is at rest, inhalation is an active process and exhalation is a passive process.

The diaphragm is not the only muscle that can change the volume of the thoracic cavity. Between the ribs are two sets of [intercostal muscles](#) (see [Figure 48.11C](#)). The external intercostal muscles expand the thoracic cavity by lifting the ribs up and outward. The internal intercostal muscles decrease the volume of the thoracic cavity by pulling the ribs down and inward. During strenuous exercise, the external intercostal muscles increase the volume of air inhaled, making use of the inspiratory reserve volume, and the internal intercostal muscles increase the amount of air exhaled, making use of the expiratory reserve volume. The abdominal muscles can also aid in breathing. When they contract, they cause the abdominal contents to push up on the diaphragm and thereby contribute to the expiratory reserve volume.

intercostal muscles Muscles between the ribs that can augment breathing movements by elevating and suppressing the rib cage.

Remember that ventilation and perfusion work together to maximize the partial pressure gradients across the alveolar membranes (see [Figure 48.11D](#)). Ventilation delivers O₂ to the environmental side of the exchange surface, where it diffuses across and is swept away by the perfusing blood, which carries it to the tissues. The reverse is true for CO₂. Perfusion delivers CO₂ to the exchange surface, where it diffuses across and is swept away by ventilation.

48.3 recap

The mammalian respiratory system consists of a highly branching system of airways that lead to alveoli—the gas exchange surfaces. Respiratory muscles ventilate the alveoli by creating pressure differences between the lungs and the outside air. CO₂ and O₂ are exchanged across thin capillary and alveoli walls by diffusion.

learning outcomes

You should be able to:

- Explain the roles of surface tension and surfactant in breathing.
- Explain how changes in volume and pressure in the thoracic cavity are involved in ventilation.
- Describe the changes (in arbitrary units) in tension between the pleural membranes and the pressure in the alveoli, and air flow during a breathing cycle.

1. Why do some premature newborns have difficulty breathing?
2. Why does a puncture wound of the chest cause a collapsed lung?
3. In the breathing cycle, what is the alveolar pressure when the tension between the pleural membranes is maximal? Explain your answer.

Having discussed how respiratory gases get to and from the environmental side of the gas exchange membranes through ventilation, we will now look at how these gases get to and from the internal side of those membranes through perfusion.

48.4 Respiratory Gases Are Transported by the Blood

Perfusion of the lungs is one of the functions of the circulatory system. The circulatory system uses a pump (the heart) and a network of vessels to transport blood around the body. Circulatory systems are the subject of [Chapter 49](#), so here we will discuss only one aspect of perfusion: how blood transports respiratory gases.

focus your learning

The protein hemoglobin in red blood cells binds, transports, and releases O_2 to the tissues of the body.

Factors influencing the affinity of hemoglobin for oxygen include its chemical composition, the P_{O_2} in the blood plasma, the blood pH, and the presence of 2,3-bisphosphoglyceric acid.

Most of the carbon dioxide produced by body cells is transported from tissues to alveoli in the form of bicarbonate ions dissolved in blood plasma.

The liquid part of blood, the plasma, carries some O_2 in solution, but its ability to transport this nonpolar molecule is limited. The blood plasma of a human can contain in solution about 3 mL of O_2 per liter of plasma, which is inadequate to support even basal metabolism. However, the blood of vertebrates and many invertebrates, contains molecules that bind and release O_2 and thus augment its transport capacity. These molecules pick up O_2 where PO_2 is high and release it where PO_2 is lower. There are many O_2 transport molecules in the animal kingdom, but in vertebrates this role is played by hemoglobin, a protein contained in red blood cells (RBCs). The percent of the blood volume consisting of RBCs is called the [hematocrit](#). The hematocrit of human males averages 45 percent and that of females 40 percent. Hemoglobin increases the capacity of blood to carry 60 times more oxygen than it could carry in solution, making high rates of metabolism possible.

hematocrit The proportion of the blood volume that consists of red blood cells.

Red blood cells are produced in the bone marrow

In humans, about 25 percent of the cells in the body are RBCs. They are produced in the bone marrow at a rate of about 2 million per second, and they circulate around the body for 100-120 days before they are destroyed. Each circuit around the body takes about a minute when at rest. RBCs are among the smallest cells of the body. They have to pass through the tiniest blood vessels, the capillaries. To be so small yet carry a lot of hemoglobin (at least 25% of their volume), RBCs lose their nuclei and most cell organelles prior to being released into the circulation. Because they have no mitochondria, they depend on [glycolysis](#) for energy.

glycolysis (gly kol' li sis) [Gk. *gleukos*: sugar + *lysis*: break apart] The enzymatic breakdown of glucose to pyruvic acid.

Hemoglobin combines reversibly with O₂

RBCs contain enormous numbers of hemoglobin molecules. **Hemoglobin** is a protein consisting of four polypeptide subunits, each of which surrounds a heme group—an iron-containing ring structure that can reversibly bind a molecule of O₂. Thus each hemoglobin molecule can bind and release up to four O₂ molecules, enabling the blood to carry a large amount of O₂ to the body's tissues.

hemoglobin (hee' mo glow bin) [Gk. *heama*: blood + L. *globus*: globe] Oxygen-transporting protein found in the red blood cells of vertebrates (and found in some invertebrates).

Hemoglobin's ability to pick up or release O₂ depends on the ^PO₂ in its environment. When the ^PO₂ of the blood plasma is high, as it usually is in the lung capillaries, each hemoglobin molecule can carry its maximum load of four O₂ molecules. As the blood circulates through the rest of the body, it releases some of the O₂ it carries when it encounters lower ^PO₂ values in tissues.

The relationship between ^PO₂ and the amount of O₂ bound to hemoglobin is not linear but S-shaped (sigmoidal). The hemo- globin-oxygen binding/dissociation curve reflects interactions between the four subunits of the hemoglobin molecule. At low PO₂ values, only one subunit will bind an O₂ molecule (**Figure 48.12A**). When it does so, the shape of that subunit changes, altering the quaternary structure of the entire hemoglobin molecule. That structural change makes it easier for the other subunits to bind an O₂ molecule; that is, their O₂ *affinity* is increased. Therefore a smaller increase in PO₂ is necessary to get the hemoglobin molecule to bind a second O₂ molecule (that is, to become 50% saturated) than was necessary to get it to bind one O₂ molecule (to become 25% saturated). This change in affinity is reflected in the increased steepness of the O₂-binding curve. The influence of O₂ binding/dissociation by one subunit on the O₂ affinity of the other subunits is called **positive cooperativity**.

Figure 48.12 Binding of O_2 to Hemoglobin Depends on P_{O_2} **(A)** The sigmoidal shape of the hemoglobin-oxygen binding/dissociation curve reflects positive cooperativity among hemoglobin's subunits. **(B)** Hemoglobin in blood leaving the lungs is 100 percent saturated (four O_2 molecules are bound to each hemoglobin molecule). Most hemoglobin molecules drop only one of their four O_2 molecules as they circulate through the body and are still 75 percent saturated when the blood

returns to the lungs. The steep portion of this O₂-binding/dissociation curve comes into play when tissue P_{O₂} falls below 40 mm Hg, which is a normal mixed venous blood P_{O₂}.

positive cooperativity Occurs when a molecule can bind several ligands and each one that binds alters the conformation of the molecule so that it can bind the next ligand more easily. The binding of four molecules of O₂ by hemoglobin is an example of positive cooperativity.

Once the third O₂ molecule is bound, the relationship seems to change, as a larger increase in P_{O₂} is required for the hemoglobin to reach 100 percent saturation. This upper bend of the sigmoid curve is due to a probability phenomenon. The closer we get to having all subunits occupied, the less likely it is that any particular O₂ molecule will find a place to bind. Therefore it takes a relatively greater P_{O₂} to achieve 100 percent saturation.

The O₂-binding/dissociation properties of hemoglobin help get O₂ to the tissues that need it most ([Figure 48.12B](#)). In the lungs, where the P_{O₂} is about 100 mm Hg, hemoglobin is 100 percent saturated. The P_{O₂} in blood returning to the heart from the body (at rest) is usually about 40 mm Hg. You can see that at this P_{O₂} the hemoglobin is still about 75 percent saturated. This means that as the blood circulates around the body, it releases only about one in four of the O₂ molecules it carries. This system seems inefficient, but because the hemoglobin keeps 75 percent of its O₂ in reserve, it can meet the demands of highly active tissues.

When a tissue becomes starved of O₂ and its local P_{O₂} falls below 40 mm Hg, the hemoglobin flowing through that tissue is on the steep portion of its binding/dissociation curve. That means relatively small decreases in P_{O₂} below 40 mm Hg will result in the release of lots of O₂ to the tissue. Thus hemoglobin is very effective in making O₂ available to tissues precisely when and where it is needed most.

The O₂ transport function of hemoglobin can rapidly and tragically be disrupted by a common by-product of incomplete combustion: carbon monoxide (CO). If CO from a faulty heating system, engine exhaust, or burning charcoal accumulates in a closed space, the results can be deadly. Because CO binds to hemoglobin with a 240-fold higher affinity than O₂, it can prevent hemoglobin from transporting O₂. In the United States, up to 500 people die each year from CO poisoning.

Activity 48.2 **Hemoglobin Loading Simulation** www.Life11e.com/ac48.2

Myoglobin holds an O₂ reserve

Muscle cells have their own O₂-binding molecule, [myoglobin](#). Myoglobin consists of just one polypeptide chain associated with an iron-containing ring structure that can bind one O₂ molecule. ***Myoglobin** has a higher affinity for O₂ than hemoglobin does, so it picks up and holds O₂ at P_{O₂} values at which hemoglobin is releasing its bound O₂ ([Figure 48.13](#)).

myoglobin (my' oh globe' in) [Gk. *mys*: muscle + L. *globus*: sphere] An oxygen-binding molecule found in muscle. Consists of a heme unit and a single globin chain; carries less oxygen than hemoglobin.

Figure 48.13 Oxygen-Binding Adaptations Myoglobin and the different hemoglobins have different O₂-binding properties adapted for different circumstances. Fetal hemoglobin, for example, has a higher affinity for O₂ than does adult hemoglobin, facilitating O₂ transfer in the placenta. When high metabolism lowers the pH of the blood, or low O₂ increases bisphosphoglyceric acid (BPG), hemoglobin releases more of its O₂.

Q: How would the breathing of some carbon monoxide affect the hemoglobin-oxygen binding curve?

 Activity 48.3 Oxygen-Binding Curves www.Life11e.com/ac48.3

Myoglobin facilitates the diffusion of O₂ in muscle cells and provides an O₂ reserve for times when metabolic demands are high and blood flow is interrupted. Interruption of blood flow in muscles is common because contracting muscles squeeze blood vessels. When tissue P_O₂ values are low and hemoglobin can no longer supply more O₂, myoglobin releases its bound O₂. Diving mammals such as seals have high concentrations of myoglobin in their muscles, which is one reason they can stay under water for so long (**Investigating Life: Seals Are Champion Breath-Hold Divers**). Even in non-diving animals, muscles called on for extended periods of work frequently have more myoglobin than do muscles that are used for short, intermittent periods, as noted in [Key Concept 47.2](#).

Hemoglobin's affinity for O₂ is variable

Various factors influence the O₂-binding/dissociation properties of hemoglobin, thereby influencing O₂ delivery to tissues. Three of these factors are the chemical composition of the hemoglobin, the blood pH, and the presence of 2,3-bisphosphoglycerate (BPG) in RBCs.

HEMOGLOBIN COMPOSITION

There is more than one type of hemoglobin because the chemical composition of the polypeptide chains that form the hemoglobin molecule varies. The normal hemoglobin of adult humans has two each of two kinds of polypeptide chains—two α-globin chains and two β-globin chains. This normal adult hemoglobin has the O₂-binding characteristics shown in [Figure 48.13](#).

Before birth, the human fetus has a different form of hemoglobin, consisting of two α -globin and two γ -globin chains. The functional difference between fetal and adult hemoglobin is that fetal hemoglobin has a higher affinity for O_2 . Therefore the fetal hemoglobin-oxygen binding/dissociation curve is shifted to the left compared with the adult curve (see [Figure 48.13](#)). You can see from these curves that if both types of hemoglobin are at the same P_{O_2} (as they are in the placenta), fetal hemoglobin will pick up O_2 that the adult hemoglobin releases. This difference in O_2 affinities enables the efficient transfer of O_2 from the mother's blood to the fetus's blood.

HEMOGLOBIN AND pH

The O_2 -binding properties of hemoglobin are also influenced by physiological conditions. The influence of pH on the function of hemoglobin is known as the **Bohr effect**. As blood passes through metabolically active tissue such as exercising muscle, it picks up acidic metabolites. As a result, blood pH falls. The excess H^+ ions bind preferentially to deoxygenated hemoglobin and decrease its affinity for O_2 , and the O_2 -binding/dissociation curve of hemoglobin shifts to the right (see [Figure 48.13](#)). This shift means the hemoglobin will release more O_2 in tissues where pH is low—another way that O_2 is supplied where and when it is most needed.

Bohr effect A shift in the O_2 -binding curve of hemoglobin in response to excess H^+ ions such that the hemoglobin releases more O_2 in tissues where pH is low.

2,3-BISPHOSPHOGLYCERATE

1,3-BPG is an intermediate in glycolysis (see p. 177), and therefore an important source of energy for cells. However, 1,3-BPG can be converted to 2,3-BPG by an enzyme in the RBC. 2,3-BPG is an important regulator of hemoglobin function. Like excess H^+ , 2,3-BPG reversibly combines with deoxygenated hemoglobin and lowers its affinity for O_2 . The result is that at any P_{c*} hemoglobin releases more of its bound O_2 than it otherwise would. In other words, 2,3-BPG shifts the O_2 -binding/ dissociation curve of mammalian hemoglobin to the right.

When humans go to high altitudes, or when they cease being sedentary and begin to exercise, the level of 2,3-BPG in their RBCs goes up, making it easier for hemoglobin to deliver more O_2 to tissues. During pregnancy, a woman has about a 30 percent increase in 2,3-BPG, which makes more O_2 available in the placenta to be picked up by the fetal hemoglobin. In addition, fetal hemoglobin has a left-shifted O_2 -binding/dissociation curve because its γ -globin chains have a lower affinity for 2,3-BPG than do the β -globin chains of adult [hemoglobin.in](#) 2,3-BPG, which makes more O_2 available in the placenta to be picked up by the fetal hemoglobin. In addition, fetal hemoglobin has a left-shifted O_2 -binding/dissociation curve because its γ -globin chains have a lower affinity for 2,3-BPG than do the β -globin chains of adult [hemoglobin.in](#) 2, 3-BPG, which makes more O_2 available in the placenta to be picked up by the fetal hemoglobin. In addition, fetal hemoglobin has a left-shifted O_2 -binding/dissociation curve because its γ -globin chains have a lower affinity for 2,3-BPG than do the β -globin chains of adult [hemoglobin.in](#) 2,3-BPG, which makes more O_2 available in the placenta to be picked up by the fetal hemoglobin. In addition, fetal hemoglobin has a left-shifted O_2 -binding/dissociation curve because its γ -globin chains have a lower affinity for 2,3-BPG than do the β -globin chains of adult hemoglobin.

experiment

Original Paper: Castellini, M. A., G. L. Kooyman and P. J. Ponganis. 1992. Metabolic rates of freely diving Weddell seals: Correlations with oxygen stores, swim velocity, and diving duration. *Journal of Experimental Biology* 165: 181–194.

Weddell seals live near the edges of the ice in Antarctica where they feed by diving in the surrounding ocean. The ice-covered ocean presents a unique opportunity to study the diving and breathing behaviors of these seals if they have to return to the same breathing hole in the ice.

QUESTION► How do metabolic requirements of a freely diving seal correlate with its oxygen stores?

METHOD

1. Transport Weddell seals several kilometers away from the ice edge, but still on the extensive Antarctic ice sheet.
2. Fit the seals with distance and depth gauges to calculate the metabolic costs of individual dives.
3. Make a hole in the ice and release the seals so they can return to the sea through the hole.
4. Allow the seals to dive and feed naturally.
5. When seals return to the hole to breathe, measure O_2 consumption and CO_2 release and determine each seal's metabolic rate (MR).

RESULTS

Most dives were only a few minutes long, but many were over 30 minutes and the longest was 82 minutes. MR was also measured when the seals rested and slept. Seals frequently do not breathe during sleep. The longest sleep episode without breathing was 13.5 minutes.

Condition	Mean MR (mL O_2 /min kg) ($\pm$ SD)
Rest	4.1 (0.3)
Sleep	3.5 (0.6)
All dives	4.5 (0.9)
Short dives	5.0 (0.9)
Long dives	3.4 (0.6)

CONCLUSIONS►

1. There were no significant differences in MR during rest, sleep, and the mean for all dives taken together. The relatively consistent measurements of MR indicate a very low metabolic cost of diving and activities during the dives. Going from resting to diving resulted in only a 10% increase in MR. (In humans, by contrast, going from resting to standing involves a 16% increase in MR.)
2. MRs during long dives were lower than at rest, but MRs during short dives (<15 minutes) were significantly higher than during long dives, indicating the capacity of the seals to conserve O_2 supplies to extend dive duration.

work with the data

How do the seal's oxygen stores compare with its oxygen demands? To calculate the oxygen reserves of a Weddell seal, we have to assess the amount of oxygen in its blood and in the myoglobin in its muscles at the beginning of the dive. The amount of oxygen in its lungs is irrelevant since seals exhale before diving, so there is little oxygen available in its alveoli during the dive.

The problem requires calculating the amount of O_2 in the arterial and venous blood and myoglobin at the beginning of the dive that is available to support the seal's MR.

Assume the following:

- Average body mass: 355 kg
- Blood volume: 14.8% of mass (7% in humans)
- Hematocrit: 58% (human averages 42%)
- Hemoglobin content of red blood cells: 23.7%
- O_2 holding capacity of hemoglobin: 1.34 mL/g
- Blood: 34% is arterial, 95% saturated at beginning of dive, can desaturate to 20%

Available O_2 in arterial blood is calculated as follows:

Total arterial blood = $355 \text{ kg} \times 0.148 \times 0.34 = 17.9 \text{ kg}$

Total arterial hemoglobin = $17.9 \text{ kg} \times 0.58 \times 0.24 = 2.49 \text{ kg}$

Maximum O_2 content = 3.34 L

Arterial O_2 available = $3.34 \times (95\% - 20\%) = 2.5 \text{ L}$

QUESTIONS►

1. Calculate the available O_2 in the venous blood. Assume venous blood is 66% of total blood volume, and it is 90% saturated at the beginning of the dive and can desaturate to 0%.
2. Calculate the available O_2 in myoglobin. Assume 33% of body mass is muscle, myoglobin content of seal muscle is 45 g/kg (20–25 g/kg for humans), and O_2 holding capacity of myoglobin is 1.34 mL O_2 /g.
3. What are the total O_2 reserves at the beginning of the dive?
4. Given the MR values found in the experiment, what do you predict would be the maximum duration of no breathing during sleep?
5. Using the table of MR values for all dives in the results portion of the experiment, predict the maximum duration of a Weddell seal dive.

A similar **work with the data** exercise may be assigned in **LaunchPad**.

Most CO₂ is transported as bicarbonate ions in the blood

Delivering O₂ to tissues is only half the respiratory function of blood. Blood also carries CO₂, a metabolic waste product, away from tissues ([Figure 48.14](#)). CO₂ is highly soluble and readily diffuses through cell membranes, moving from its site of production in the tissues into the blood, where PCO₂ is lower. However, only about 5 percent of the CO₂ carried by the blood is dissolved CO₂. About 20 percent of the CO₂ carried to the lungs in the blood is in chemical combination with hemoglobin. And most CO₂ produced by the tissues is transported to the lungs in the form of bicarbonate ions (HCO₃⁻). CO₂ diffusing from cells is converted to HCO₃⁻, transported to the lungs, and then converted back to CO₂ to be exhaled.

Figure 48.14 Carbon Dioxide Is Transported as Bicarbonate Ions The left panel represents the circulation through the tissues of the body where carbonic anhydrase (CA) in capillary endothelial cells and in RBCs facilitates conversion of CO₂ produced in the tissues to bicarbonate ions in the blood. The right panel shows the process reversing in the lungs as CO₂ diffuses from blood to alveolar air and is exhaled.

ion (eye' on) [Gk. *ion*: wanderer] An electrically charged particle that forms when an atom gains or loses one or more electrons.

When CO₂ dissolves in water, some of it slowly reacts with the water molecules to form carbonic acid (H₂CO₃), some of which then dissociates into a proton (H⁺) and a bicarbonate ion (HCO₃⁻). This reversible reaction is expressed as follows:

In the extracellular fluid, the reaction between CO₂ and H₂O proceeds slowly. But it is a different story in the endothelial cells of the capillaries and in the RBCs, where the enzyme **carbonic anhydrase** speeds up the conversion of CO₂ to H₂CO₃. The newly formed H₂CO₃ dissociates, and the resulting bicarbonate ions enter the plasma in exchange for Cl⁻ (see [Figure 48.14](#)). By converting CO₂ to H₂CO₃, carbonic anhydrase reduces the P_{CO2} in these cells and in the plasma, facilitating the diffusion of CO₂ from tissue cells to endothelial cells, plasma, and RBCs.

carbonic anhydrase (CA) An enzyme that catalyzes the hydration of CO_2 to produce carbonic acid.

In the lungs, the reactions involving CO_2 and bicarbonate ions are reversed. Remember that an enzyme such as carbonic anhydrase only speeds up a reversible reaction; it does not determine its direction. The direction is determined by concentrations of reactants and products. Ventilation keeps the P_{CO_2} in the alveoli low, so CO_2 diffuses from the blood plasma into the alveoli, lowering the P_{CO_2} in the blood, which favors the conversion of HCO_3^- into CO_2 . Also, the oxygenation of hemoglobin in the alveoli decreases its affinity for CO_2 , a phenomenon known as the Haldane effect.

48.4 recap

O_2 is transported from the lungs to the body's tissues in reversible combination with hemoglobin. Each hemoglobin molecule can reversibly combine with four O_2 molecules; the percent saturation of the binding sites is a function of the P_{O_2} in the hemoglobin's environment. The hemoglobin-oxygen binding/dissociation curve is shifted by the concentration of H^+ and the level of 2,3-BPG in the blood. CO_2 is transported by the blood mostly in the form of HCO_3^- .

learning outcomes

You should be able to:

- Explain the adaptive advantage of hemoglobin remaining 75 percent saturated with O_2 in mixed venous blood.
 - Explain how 2,3-BPG and pH alter the O_2 binding properties of hemoglobin, and discuss the functional significance of these changes.
 - Explain how the same enzyme, carbonic anhydrase, catalyzes both the loading of CO_2 from cells to the blood and the off-loading of CO_2 from the blood to the alveoli.
-
1. The P_{O_2} of atmospheric air at sea level is about 159 mm Hg. What is the functional significance of the fact that human hemoglobin fully saturates with O_2 at a P_{O_2} of 100 mm Hg and returns to the heart in venous blood with a P_{O_2} of about 40 mm Hg, reflecting 75 percent saturation?
 2. When red blood cells are stored in the blood bank, they will eventually use their 1,3-BPG for energy. What will be the consequence for their ability to function after transfusion into a patient?
 3. Why do HCO_3^- ions leave the red blood cells in systemic venous blood but enter red blood cells in the alveolar circulation?

We must breathe every minute of our lives, but most of us usually don't worry about it, or even think about it very often. In the next section we will examine how the regular breathing cycle is generated and controlled by the central nervous system.

***connect the concepts** In [Key Concept 9.1](#), glycolysis is described as a sequence of reactions that by the sixth step has converted one molecule of glucose to two molecules of 1,3-bisphosphoglycerate and by the tenth step to two molecules of pyruvate. However, some of the 1,3-bisphosphoglycerate can be enzymatically converted to 2,3-bisphosphoglycerate which plays an important role in regulating the oxygen-binding properties of hemoglobin, as you will learn below.

***connect the concepts** The evolutionary relationships between myoglobin and the various hemoglobin subunits is shown in [Figure 23.10](#)

48.5 Breathing Is Homeostatically Regulated

Breathing is an involuntary function of the central nervous system (CNS). The breathing pattern is adjusted around other activities (such as speech and eating), and breathing rates change to match the metabolic demands of the body. How is this accomplished?

focus your learning

The breathing pattern of inhalation followed by exhalation is controlled by a neural circuit in the brainstem.

Breathing is regulated by feedback mechanisms involving CO₂ sensitive cells in the brain and O₂ sensitive cells in the great arteries.

Brain chemosensitive cells sense CO₂ levels through changes in hydrogen ion concentration, whereas nodes in the aorta and the carotid arteries are sensitive to blood O₂ levels.

The basic breathing rhythm is an involuntary function that is modified by feedback information that conveys the body's need for an adequate O₂ supply and CO₂ elimination.

Breathing is controlled in the brainstem

Breathing is driven by a rhythm-generating neural circuit in the brainstem, but where? Breathing ceases if the spinal cord is severed in the neck region, showing that breathing is generated in the brain. If the brainstem is cut just above the pons, breathing is normal. If the brainstem is cut between the pons and the medulla (the segment of the brainstem just above the spinal cord), the breathing pattern becomes irregular ([Figure 48.15](#)). Electrophysiological recordings reveal a group of respiratory motor neurons in the dorsal medulla that increase their firing rates just before an inhalation begins. The axons of these neurons leave the CNS in the neck region to form the phrenic nerve, which innervates the diaphragm. As more and more of these neurons fire—and fire faster and faster—the diaphragm contracts. All of a sudden the neurons stop firing, the diaphragm relaxes, and exhalation begins. Exhalation is usually a passive process that depends on the elastic recoil of the lung tissues. Another group of respiratory motor neurons is found in the ventral medulla that becomes active when breathing demand is high. These motor neurons communicate through thoracic spinal nerves to the intercostal muscles. By expanding and contracting the rib cage, the intercostal muscles increase both the inhalation and the exhalation volumes.

Figure 48.15 Breathing Is Controlled in the Brainstem Basic breathing rhythm is generated in the medulla and is modified by neurons in or above the pons.

Media Clip 48.1 **Sea Bed Hunting on One Breath** www.Life11e.com/mc48.1

Neurons in the lower region of the pons help regularize the basic respiratory rhythm. Still higher brain areas modify breathing to accommodate speech, ingestion of food, coughing, and emotional states.

Regulating breathing requires feedback

When breathing or metabolism changes, the P_{O_2} and P_{CO_2} in the blood change as well. It is reasonable to surmise that the blood levels of one or both of these gases provide feedback information to the breathing rhythm generator in the medulla. Humans and other mammals are remarkably insensitive to falling levels of O_2 in arterial blood but are extremely sensitive to increases in CO_2 . That is, arterial P_{O_2} can deviate considerably from normal without causing much of an increase in ventilation rate, but even a small rise in arterial P_{CO_2} causes a large increase in ventilation (**Figure 48.16**). This relationship is reversed for water-breathing animals, in which O_2 is the primary feedback stimulus for gill ventilation.

Figure 48.16 Carbon Dioxide Affects Breathing Rate The breathing mechanism is more sensitive to increased levels of CO_2 in arterial blood than to decreased amounts of O_2 .

The lack of O_2 sensitivity in humans was tragically demonstrated by an accident at the Kennedy Space Center in 1981 prior to the first flight of the Space Shuttle Program. The space shuttle *Columbia* was being prepared for launch, and to reduce the danger of fire, the engine compartment was purged with nitrogen and sealed. Unaware of the nitrogen, workers opened a hatch to the compartment for inspection. The first worker to enter became unconscious, and others followed him in a rescue attempt. Three of these workers died, and two others who were stricken recovered. When exposed to lack of oxygen, there is no alerting, emergency response—there is simply loss of consciousness.

Where are partial pressures of gases in the blood sensed? The major site of P_{CO_2} sensitivity is an area on the ventral surface of the medulla. The primary sensitivity of these chemosensitive cells is not, however, to CO_2 . It is H^+ ions that stimulate these cells. The H^+ ion concentration in the environment of these cells is a direct reflection of the P_{CO_2} of the blood. When the P_{CO_2} of the blood is higher than that of the extracellular fluid in this area, CO_2 diffuses out of the blood. This CO_2 interacts with H_2O in the plasma to form carbonic acid (H_2CO_3), which dissociates into H^+ ions and HCO_3^- ions (see [Figure 48.14](#), which describes this same reaction in the RBCs). It is the H^+ ions produced by the dissociation of carbonic acid that stimulate the chemosensitive cells that increase respiratory gas exchange. Thus even though we measure blood P_{CO_2} as the

stimulus for breathing, the major stimulus is an increase in H^+ ion concentration (lowered pH).

We do have some physiological sensitivity to blood PO_2 in nodes of neural tissue on the large blood vessels leaving the heart: the aorta and the carotid arteries (**Figure 48.17**). These **carotid bodies** and **aortic bodies** are chemosensors. If the blood supply to these structures decreases, or if the blood PO_2 falls dramatically, the chemosensors are activated and send nerve impulses to the breathing control center. Although we are not very sensitive to changes in blood PO_2 , the carotid and aortic bodies can stimulate increases in breathing during exposure to high altitudes or when blood volume or blood pressure is very low. Also, there is a synergism between CO_2 and O_2 sensing. When blood P_{CO_2} increases, there is an increased sensitivity to low O_2 , and vice versa.

Figure 48.17 Feedback Information Controls Breathing The body uses feedback information from chemosensors in the great arteries leaving the heart and on the ventral surface of the medullary brainstem to match breathing rate to metabolic demand.

carotid body A chemosensor in the carotid artery that senses a decrease in blood supply or a dramatic decrease in partial pressure of oxygen in the blood.

aortic body A chemosensor in the aorta that senses a decrease in blood supply or a dramatic decrease in partial pressure of oxygen in the blood.

48.5 recap

The rhythmic contractions of the respiratory muscles that drive breathing are generated by neurons in the brainstem. Breathing is regulated predominantly in response to the P_{CO_2} of the blood. Respiratory chemosensors are cells on the ventral surface of the medulla that are sensitive to the blood P_{CO_2} , and the carotid and aortic bodies on the large arteries leaving the heart that are sensitive to the blood P_{O_2} or to a decrease in the blood they are receiving.

learning outcomes

You should be able to:

- Explain the roles of the dorsal and ventral groups of respiratory neurons in the medulla.
 - Apply knowledge about the physiological processes underlying breathing to explain the body's response to intense exercise and to decreases in P_{O_2} .
 - Describe where chemosensitive cells are located and how they participate in negative feedback control of breathing.
1. In terms of respiratory motor neurons and respiratory muscle groups, what changes occur in transitioning from breathing at rest to breathing that uses more of the lung's vital capacity?
 2. When you go rapidly to high altitude, you may experience a breathing pattern in which periods of no breathing alternate with periods of fast breathing. Explain that response in terms of diffusion gradients for O_2 and CO_2 and the feedback signals regulating breathing.
 3. Cells in the carotid and aortic bodies have high metabolic rates, and they are sensitive either to a decrease in blood flow or to a decrease in the PO_2 of the blood. How are these two facts related?

▶ investigatinglife

What adaptations make seals champion breath-hold divers?

Seals have remarkable abilities to dive deep and long and to spend only minutes at the surface to breathe between dives. In the chapter opener about elephant seals, we posed several questions that apply to all seals: Why aren't seals crushed by the water pressure at extreme depths? Why don't they get the bends? What are their O_2 demands? And what are their O_2 reserves? The answers to the first two questions are related. Only air-filled structures of the body are compressible, and the seals exhale at the beginning of a dive. Their residual volume is restricted to their airways, where gas exchanges do not occur. Thus the high pressure of the small amount of gas in their respiratory system does not drive dissolved nitrogen into their tissues. Investigating Life: Seals Are Champion Breath-Hold Divers presented metabolic rate (MR) measurements for Weddell seals resting, sleeping, and diving. No significant differences in MR for various activities were observed, leading to the conclusion that the metabolic costs of diving are quite modest. In fact, MRs during dives were only about 10 percent higher than at rest—not much different than for humans going from sitting to standing.

How is seal activity supported by such a low metabolic expenditure? And given those low MRs, how do seals maintain O_2 reserves sufficient to support them during dives? The calculations made in the work with the data exercise in Investigating Life: Seals Are Champion Breath-Hold Divers showed that the O_2 reserve of a sleeping seal would permit it to not breathe for a maximum of 12.8 minutes, which

corresponds well with the maximum episode of sleep observed — 13.5 minutes. Using the MR value for all dives, calculations show that the seals' O_2 reserves would only support dives that were under 10 minutes in duration. This means that additional adaptations enable the seal to remain active underwater for long periods at an average MR similar to what they experience during sleep.

Future directions

Recording devices attached to seals diving in nature reveal adaptations that minimize their O_2 demands during a dive. Because they exhale at the beginning of a dive, they are negatively buoyant, meaning they can drift down to depths like a falling leaf. These recordings also answered another question. Since the seals at sea dive continually day and night, when do they sleep? They spend much of their passive descent time sleeping, thus lowering their MR even more. Yet more metabolic savings are needed to enable long dives. One clue comes from measures of the seals' heart rates during dives. Their heart rates are very much reduced, a phenomenon called diving bradycardia. We will discuss diving bradycardia in the next chapter and see how it relates to seals' ability to drastically lower their MR while diving.

► 48.1 Respiratory Gas Exchange Is Governed by Physical Factors

- Most cells require a constant supply of O_2 and continuous removal of CO_2 . These **respiratory gases** are exchanged between an animal's body fluids and its environment by diffusion.

respiratory gases Oxygen (O_2) and carbon dioxide (CO_2); the gases that an animal must exchange between its internal body fluids and the outside medium (air or water).

- Fick's law of diffusion** shows how various physical factors influence the diffusion rate of gases. Adaptations to maximize respiratory gas exchange influence one or more variables of Fick's law.

Fick's law of diffusion An equation that describes the factors that determine the rate of diffusion of a molecule from an area of higher concentration to an area of lower concentration.

- In water-breathing animals, gas exchange is limited by the low diffusion rate and low amount of O_2 in water. If water temperature rises, water-breathing animals face a double bind: while O_2 in water decreases, the amount of work required to move water over the gas exchange surfaces increases. **Review Figure 48.2**
- In air, O_2 **partial pressure** (PO_2) decreases with increasing altitude.

► 48.2 Enhancing Diffusion Maximizes Respiratory Gas Exchange

- Adaptations to maximize gas exchange include increasing the surface area for gas exchange and maximizing partial pressure gradients across those exchange surfaces. Partial pressure gradients are established both by ventilating the outer surface with the respiratory medium, and perfusing the inner surface with blood.
- External and internal gills** are adaptations for gas exchange with water. **Lungs and tracheae** are adaptations for gas exchange with air. **Review Figures 48.3, 48.4**
- The gills of fish have large gas exchange surface areas that are ventilated continuously and unidirectionally with water. The **countercurrent flow** of blood helps increase the efficiency of gas exchange. **Review Figures 48.5, 48.6**

countercurrent flow An arrangement that promotes the maximum exchange of heat, or of a diffusible substance, between two fluids by having the fluids flow in opposite directions through parallel vessels close together.

- The gas exchange system of birds includes **air sacs** that communicate with the lungs but are not used for gas exchange. Air flows unidirectionally through bird lungs; gases are exchanged in air capillaries that run between **parabronchi**. **Review Figure 48.7**

air sacs Structures in the respiratory system of birds that receive inhaled air; they keep fresh air flowing unidirectionally through the lungs, but are not themselves gas exchange surfaces.

parabronchi Passages in the lungs of birds through which air flows.

- Each breath of air remains in a bird's respiratory system for two breathing cycles. The air sacs work as bellows to supply the air capillaries with a continuous unidirectional flow of fresh air. **Review Figure 48.8, Animation 48.1**
- In all air-breathing vertebrates except birds, breathing is **tidal**. Although the volume of air exchanged with each breath can vary considerably in tidal breathing, the inhaled air is always mixed with stale air. **Review Figure 48.9**

tidal The bidirectional form of ventilation used by all vertebrates except birds; air enters and leaves the lungs by the same route.

▶ 48.3 Humans Have Tidal Respiration

- In mammalian lungs, the gas exchange surface area provided by the millions of **alveoli** is enormous, and the diffusion path length between the air and perfusing blood is short. **Surface tension** in the alveoli would make inflation of the lungs difficult if the alveoli did not produce **surfactant**. **Review Focus: Key Figure 48.10, Activity 48.1**

surface tension The attractive intermolecular forces at the surface of liquid; an especially important property of water.

surfactant A substance that decreases the surface tension of a liquid. Lung surfactant, secreted by cells of the alveoli, is mostly phospholipid and decreases the amount of work necessary to inflate the lungs.

- Inhalation occurs when contractions of the **diaphragm** increase volume and reduce pressure in the **thoracic cavity**, thereby pulling on the **pleural membranes**. Relaxation of the diaphragm increases pressure in the thoracic cavity and results in exhalation. **Review Figure 48.11, Animation 48.2**

diaphragm (dye' uh fram) [Gk. *diaphrassein*: barricade] (1) A sheet of muscle that separates the thoracic and abdominal cavities in mammals; responsible for breathing. (2) A method of birth control in which a sheet of rubber is fitted over the woman's cervix, blocking the entry of sperm.

thoracic cavity [Gk. *thorax*: breastplate] The portion of the mammalian body cavity bounded by the ribs, shoulders, and diaphragm. Contains the heart and the lungs.

pleural membrane [Gk. *pleuras*: rib, side] The membrane lining the outside of the lungs and the walls of the thoracic cavity. Inflammation of these membranes is a condition known as pleurisy.

- During periods of heavy metabolic demands such as strenuous exercise, the **intercostal muscles**, located between the ribs, increase the volume of air inhaled and exhaled.

intercostal muscles Muscles between the ribs that can augment breathing movements by elevating and suppressing the rib cage.

▶ 48.4 Respiratory Gases Are Transported by the Blood

- O_2 is reversibly bound to **hemoglobin** in red blood cells. Each hemoglobin molecule can carry a maximum of four O_2 molecules. Because of **positive cooperativity**, hemoglobin's affinity for O_2 depends on the P_{O_2} to which the hemoglobin is exposed. Therefore hemoglobin picks up O_2 as it flows through respiratory exchange structures and gives up O_2 in metabolically active tissues. Review [Figure 48.12](#), [Activity 48.2](#)

hemoglobin (hee' mo glow bin) [Gk. *heama*: blood + L. *globus*: globe] Oxygen-transporting protein found in the red blood cells of vertebrates (and found in some invertebrates).

positive cooperativity Occurs when a molecule can bind several ligands and each one that binds alters the conformation of the molecule so that it can bind the next ligand more easily. The binding of four molecules of O_2 by hemoglobin is an example of positive cooperativity.

- **Myoglobin** serves as an O_2 reserve in muscle.

myoglobin (my' oh globe' in) [Gk. *mys*: muscle + L. *globus*: sphere] An oxygen-binding molecule found in muscle. Consists of a heme unit and a single globin chain; carries less oxygen than hemoglobin.

- There is more than one type of hemoglobin. Fetal hemoglobin has a higher affinity for O_2 than does adult hemoglobin, allowing fetal blood to pick up O_2 from the maternal blood in the placenta. Review [Figure 48.13](#), [Activity 48.3](#)
- CO_2 is transported in the blood principally as bicarbonate ions (HCO_3^-). [Review Figure 48.14](#)

► 48.5 Breathing Is Homeostatically Regulated

- The basic breathing rhythm is an involuntary function generated by neurons in the medulla and modulated by higher brain centers. The most important feedback stimulus for breathing is the level of CO_2 in the blood. [Review Figures 48.15](#), [48.16](#)
- The breathing rhythm is sensitive to feedback from chemosensors on the ventral surface of the medulla and in the **carotid** and **aortic bodies** on the large vessels leaving the heart. [Review Figure 48.17](#)

See [Activity 48.4](#) for a concept review of this chapter.

► Apply What You've Learned

Review

- 8.1 Respiratory gases diffuse from areas of higher partial pressure to areas of lower partial pressure.
- 8.1 Rising temperature decreases oxygen solubility in water and increases the metabolism of aquatic ectotherms.
- 8.2 In insects, efficient gas exchange is facilitated by an internal network of air passages.

Original Paper: Hetz, S. K. and T. J. Bradley. 2005. Insects breathe discontinuously to avoid oxygen toxicity. *Nature* 433: 516-519.

Insects' air-delivery system consists of tracheae that branch throughout the body, facilitating the exchange of O_2 and CO_2 in and out of tissues. The finest of these tubes are less than a micrometer in diameter. Tracheal openings on the body's surface are guarded by valve-like spiracles that can be opened, closed, or "fluttered."

To study tracheal function, microscopic plastic tubes were surgically inserted into the tracheae of the pupal stages of *Attacus atlas* moths. The microtubes were attached to sensors that recorded the rate of CO_2 released from the tracheae and the intratracheal concentrations of O_2 . Pupae were placed in chambers with normal atmospheric levels of gases, and the spiracle behavior, rate of CO_2 release, and O_2 concentrations in the tracheae were recorded ([Figure A](#)). Kilopascals (kPa) was the measure of gas pressure.

To test how the spiracles performed in differing atmospheric conditions and what effects this might have on the rate of CO_2 release and O_2 concentrations, researchers exposed pupae to

differing levels of atmospheric O_2 (labeled red line in graphs). They then measured levels of CO_2 release and O_2 concentrations during the fluttering stage ([Figure B](#)).

Questions

1. If $1 \text{ kPa} = 7.5 \text{ mm Hg}$, calculate the change in P_{O_2} in units of mm Hg in a typical open-close-fluttering cycle. What is the approximate mm Hg P_{O_2} in the atmosphere and inside the tracheal tubes in each of the three experiments shown in Figure B?
2. Based on your understanding of the purpose of insect tracheae, explain why the P_{O_2} rises to such a high level inside the tracheae when the spiracle is open, and then decreases over time. What effect does the fluttering of spiracles have on P_{O_2} ?
3. One function of the fluttering of spiracles might be to prevent the PO_2 from reaching a toxic level. Based on the data in Figure B, is this a viable hypothesis? Explain your answer.

Circulatory Systems

Fabrice Muamba (on the right) was a lucky survivor of cardiac arrest caused by hypertrophic cardiomyopathy, the most common cause of death among young athletes. What causes this condition, and can it be prevented or treated?

key concepts

investigatinglife

Athletes with Big Hearts

Fabrice Muamba was a much-loved and admired professional soccer player. On March 17, 2012, during a championship quarterfinal match, 23-year-old Fabrice suddenly collapsed on the field. He was immediately attended to by team physicians and a cardiologist who happened to be a spectator at the match. Fabrice received numerous defibrillator shocks, car-diopulmonary resuscitation, and was rushed to a hospital, but still his heart stopped for 78 minutes. Remarkably he survived, but there is a long list of young, fit athletes who have died from cardiac arrest during physical exertion. Sudden cardiac arrest is the most common cause of death for athletes. In most cases the cause is not a heart attack, but a condition known as hypertrophic cardiomyopathy (HCM).

Your heart is a muscular pump. At rest it beats an average of 60-70 times per minute. With each beat, it circulates about 70 milliliters of blood through your body. Without adding the increases due to work or exercise, that is 300 liters per hour, 7,200 liters per day, 2.6 million liters per year—no time-outs.

Heart failure is the leading cause of death in the United States, accounting for some one-fourth (about 600,000) of the deaths each year. Heart failure most commonly results from blockage of the blood vessels that supply the heart muscle with blood, and its risk increases with age. The most common cause of heart failure in athletes is not blocked vessels but gene mutations that affect the contractile proteins of the heart. About 1,000 such mutations have been identified, and they exist in about 1 in 500 people. Most people with one of these mutations live normally, so why are they so dangerous in athletes? The mutations decrease the efficiency of the contractions of the heart muscle, so the heart has to work much harder. Especially in athletes, the heart gets bigger to compensate for its inefficiency. The walls of the heart can get so thick that they impede the blood from leaving the heart, and the thick walls can interfere with the signals that coordinate the contractions of the heart muscle. The result is cardiac arrest. Assessment of HCM risk is improving, and many afflicted athletes are choosing to retire rather than taking a chance of dying from cardiac arrest.

Are there potential therapies that could treat HCM?

49.1 Circulatory Systems Serve Many Functions

A **circulatory system** consists of a muscular pump (the heart), a fluid (blood), and a series of conduits (blood vessels) through which the fluid can be pumped throughout the body. Heart, blood, and vessels are also known collectively as a **cardiovascular system** (Greek *kardia*, “heart,” + Latin *vasculum*, “vessel”). The function of a circulatory system is to transport things around the body. Preceding chapters discussed how circulatory systems transport heat, hormones, respiratory gases, blood cells, platelets, and cells and molecules of the immune system. Succeeding chapters will add nutrients and waste products to that list. In this section we will describe the general types of circulatory systems found in animals.

circulatory system A physiological system consisting of a muscular pump (heart), a fluid (blood or hemolymph), and a series of conduits (blood vessels) that transports materials around the body.

cardiovascular system [Gk. *kardia*: heart + L. *vasculum*: small vessel] The heart, blood, and vessels are of a circulatory system.

focus your learning

A circulatory system functions to transport materials around the body.

Small or thin aquatic organisms may not have circulatory systems, and the needs of their cells are served by direct exchange with the environment.

Circulatory systems use a muscular heart to distribute extracellular fluid throughout the body to transport nutrients, respiratory gases, wastes, and other materials.

Closed circulatory systems allow more rapid flow and differential control of blood flow to different tissues.

Some animals do not have a circulatory system

Single-celled organisms serve all of their needs through direct exchanges with the environment. Such organisms are found mostly in aquatic or very moist terrestrial environments. Similarly, many multicellular aquatic organisms are small or thin enough that all of their cells are close to the external environment. Such species may not have a circulatory system because nutrients, respiratory gases, and wastes can diffuse directly between the cells of their bodies and the environment.

The cells of some larger aquatic multicellular animals without a circulatory system are served by highly branched central cavities called **gastrovascular systems** that bring the external environment into the animal. All the cells of a sponge are in contact with, or very close to, the water that surrounds the animal and circulates through its central cavity (see [Figure 48.1B](#)). Very small animals without a circulatory system can maintain high levels of metabolic activity, but larger animals without a circulatory system such as sponges, jellyfishes, and flatworms tend to be inactive, slow, or even sedentary. Large, active animals require circulatory systems.

gastrovascular system A branching body cavity in Cnidaria and Platyhelminthes that has one opening to the environment and serves to digest food and distribute nutrients to the body.

Circulatory systems can be open or closed

The cells of large, mobile animals are supported by extracellular fluid. All requirements of cells—oxygen, fuel, nutrients, essential molecules—come from that fluid, and the waste products of cell metabolism go into it. Circulatory systems have muscular chambers, or **hearts**, that move the extracellular fluid through the body. In open circulatory systems, extracellular fluid is the same as the fluid in the circulatory system and is called **hemolymph**. This fluid leaves the vessels of the circulatory system, percolates between cells and through tissues, and then flows back into the heart or vessels of the circulatory system to be pumped out again. In contrast, closed circulatory systems completely contain the circulating fluid (blood) in a continuous system of vessels. Blood cells and large molecules stay within the system, but water and low-molecular-weight solutes leak out of the smallest vessels, the capillaries, which are highly permeable.

heart In circulatory systems, a muscular pump that moves extracellular fluid around the body.

hemolymph The extracellular fluid in closed circulatory systems.

In animals with a closed circulatory system, **extracellular fluid** refers to both the fluid in the circulatory system and the fluid outside it. The fluid in the circulatory system is the blood plasma; the *** extracellular fluid** outside the circulatory system is the **interstitial fluid**. A 70-kilogram person has a total extracellular fluid volume of about 14 liters. Less than a quarter of it—about 3 liters—is the blood plasma.

extracellular fluid In closed circulatory systems refers to the fluid in the circulatory system and the fluid outside it.

interstitial fluid Extracellular fluid that is not contained in the vessels of a circulatory system.

Open circulatory systems move extracellular fluid

Open circulatory systems are found in arthropods, mollusks, and some other invertebrate groups. In these systems a heart moves the hemolymph through vessels leading to different regions of the body. The fluid leaves the vessels to filter through the tissues before returning to the heart. In the arthropod shown in **Figure 49.1A**, the fluid returns directly to the heart through openings called ostia. Ostia have valves that allow hemolymph to enter the relaxed heart but prevent it from flowing in the reverse direction when the heart contracts. In a mollusk such as a clam, open vessels collect hemolymph from different regions of the body and return it to the heart (**Figure 49.1B**).

open circulatory system Circulatory system in which extracellular fluid leaves the vessels of the circulatory system, percolates between cells and through tissues, and then flows back into the circulatory system to be pumped out again. (Contrast with closed circulatory system.)

(A) Arthropod circulation

A muscular, tubular heart pumps hemolymph to different body regions. The hemolymph percolates through tissues and re-enters the heart through openings called ostia.

(B) Mollusk circulation

In mollusks, a system of vessels drains the intercellular spaces and returns hemolymph to the heart.

(C) Annelid worm circulation

In annelids, muscular hearts pump blood through a system of closed vessels.

Figure 49.1 Circulatory Systems Arthropods, illustrated here by an insect **(A)**, and mollusks such as clams **(B)** have an open circulatory system. Hemolymph is pumped by a tubular heart and directed to different regions of the body through vessels that open into intercellular spaces. **(C)** Annelids such as earthworms have a closed

circulatory system, in which the cellular and macromolecular elements of the blood are confined in a system of vessels, and the blood is pumped through those vessels by one or more muscular hearts. Earthworms exchange respiratory gases across their skin. The circulation distributes those gases between the skin and the deeper tissues.

Lest you think that open circulatory systems are inefficient and can support only sluggish lifestyles such as those of mollusks, remember that crabs scuttling along the beach, yellow jackets buzzing around your picnic, and scorpions dashing across the desert all have open circulatory systems.

Closed circulatory systems circulate blood through a system of blood vessels

In [closed circulatory systems](#), blood vessels separate blood from interstitial fluid. Blood is pumped through this vascular system by one or more hearts, and cellular and macromolecular components of the blood never leave the vessels. Closed circulatory systems characterize vertebrates and some invertebrate groups, among them annelids.

closed circulatory system Circulatory system in which the circulating fluid is contained within a continuous system of vessels. (Contrast with open circulatory system.)

A simple example of a closed circulatory system is that of the earthworm ([Figure 49.1C](#)). One large ventral blood vessel carries blood from the worm's anterior end to its posterior end. Smaller vessels branch off and transport the blood to even smaller vessels serving the tissues in each body segment. In the smallest vessels, respiratory gases, nutrients, and metabolic wastes diffuse between the blood and interstitial fluid. The blood then flows from these vessels into larger vessels that lead into one large dorsal vessel that carries the blood from the posterior to the anterior end of the body. Five pairs of muscular vessels connect the large dorsal and ventral vessels in the anterior end, thus completing the circuit.

The dorsal vessel and the five connecting vessels serve as hearts for the earthworm; their contractions keep the blood circulating. The direction of circulation is determined by one-way valves in the dorsal vessel.

Closed circulatory systems have several advantages compared with open systems:

Fluid can flow more rapidly through vessels than through intercellular spaces and can therefore transport things to and from tissues more rapidly.

By changing the diameter (and hence the resistance) of specific vessels, closed systems can control the flow of blood to selective tissues and organs to match their needs.

Specialized cells and large molecules that aid in transporting hormones, nutrients, and oxygen can be kept in the vessels but can drop their cargo in the tissues where it is needed.

With all of these “advantages” of closed circulatory systems, you might wonder how some species with open circulatory systems can sustain such high levels of activity. In the case of insects, the answer is clear: insects do not depend on their circulatory systems for respiratory gas exchange (see [Figure 48.4](#)).

49.1 recap

Circulatory systems consist of a pump and an open or closed set of vessels through which a fluid transports oxygen, nutrients, wastes, and a variety of other substances. Flow to and from tissues in closed systems of vessels can be more rapid and can be directed to specific tissues according to their needs.

learning outcomes

You should be able to:

- Describe the diverse functions of circulatory systems.
- Explain why some animals can function without a circulatory system.
- Describe the differences among hemolymph, blood plasma, and interstitial fluid.
- Identify features that make a closed circulatory system more efficient than an open circulatory system.

-
1. Describe three ways that circulatory systems support exercising muscles.
 2. A sponge is neither small nor thin. How can it survive without a circulatory system?
 3. Explain the importance of extracellular fluid in large mobile animals.
 4. How does a closed circulatory system facilitate the fight-or-flight response?

Our overview of the open and closed systems found among invertebrates introduced some basic concepts about circulatory systems. Next we will turn to describing the closed circulatory systems of vertebrates.

***connect the concepts** [Key Concept 39.2](#) and [Figure 39.4](#) describe the different extracellular fluid compartments that constitute the internal environment that supports all of the metabolic needs of the cells of the body.

49.2 Vertebrate Circulatory Systems Evolved from Single to Double Circuits

Vertebrates have a closed circulatory system and a heart with two or more chambers. When a heart chamber contracts, it squeezes the blood, putting it under pressure. Blood then flows out of the heart and into vessels, where pressure is lower. Resistance to flow in the vessels dissipates the pressure imparted to the blood by the heart. One-way valves prevent backflow of blood as the heart cycles between contraction and relaxation. Comparisons of the circulatory systems of different vertebrates reveals that as circulatory systems become more complex, the blood that flows to the gas exchange organs (gills or lungs; see [Figure 48.3](#)) becomes increasingly separated from the blood that flows to the rest of the body.

focus your learning

The circulatory system in fishes is organized as a single circuit in which blood is pumped by a four-chambered heart through the gills and then to the other organs of the body.

The lungfish is a transitional form in the evolution of a single blood-flow circuit into separate pulmonary and systemic circuits in other vertebrates.

Ectothermic reptiles have the ability to control blood flow to the pulmonary circuit, enabling them to conserve energy when they are not breathing.

Separation of pulmonary and systemic circulations maximizes oxygen transport to body cells and gas exchange in respiratory tissues, and allows the two circuits to operate at different pressures.

In fishes, the phylogenetically oldest vertebrates, blood is pumped from the heart to the gills and then to the tissues of the body and back to the heart—a single circuit. In birds and mammals, blood is pumped from the heart to the lungs and back to the heart in a [pulmonary circuit](#), and then from the heart to the rest of the body and back to the heart in a [systemic circuit](#). In amphibians and ectothermic reptiles we see various adaptations that incompletely separate the blood flow into pulmonary and systemic circuits.

pulmonary circuit The portion of the circulatory system by which blood is pumped from the heart to the lungs or gills for oxygenation and back to the heart for distribution. (Contrast with systemic circuit.)

systemic circuit Portion of the circulatory system by which oxygenated blood from the lungs or gills is distributed throughout the rest of the body and returned to the heart. (Contrast with pulmonary circuit.)

Both pulmonary and systemic circuits begin with vessels called [arteries](#) that carry blood away from the heart. Arteries branch into smaller [arterioles](#) that feed blood into capillary beds. [Capillaries](#) are tiny, thin-walled vessels where materials are exchanged between blood and the interstitial fluid. Small vessels called [venules](#) drain capillary beds. The venules join to form the larger [veins](#) that ultimately deliver blood back to the heart.

arteriole A small blood vessel arising from an artery that feeds blood into a capillary bed.

arteriole A small blood vessel arising from an artery that feeds blood into a capillary bed.

capillaries [L. *capillaris*: hair] Very small tubes, especially the smallest blood-carrying vessels of animals between the termination of the arteries and the beginnings of the veins.

Capillary beds are networks of capillaries where materials are exchanged between the blood and the interstitial fluid.

venule A small blood vessel draining a capillary bed that joins others of its kind to form a vein. (Contrast with arteriole.)

vein [L. *vena*: channel] A blood vessel that returns blood to the heart. (Contrast with artery.)

We can trace the evolutionary history of vertebrate circulatory systems by comparing the circulatory systems of fishes, lungfishes, amphibians, reptiles (including crocodilians), and mammals.

Circulation in fishes is a single circuit

The fish heart has four chambers that are connected in series. Blood returning from all parts of the body collects in a **sinus venosus** that feeds into the muscular **atrium**. The atrium pumps blood into the more muscular chamber, the **ventricle**. Contraction of the ventricle pushes blood into the last chamber, the **bulbus arteriosus**, a highly elastic chamber. The pressure imparted to the blood by the ventricle stretches the bulbus arteriosus, and its elastic recoil dampens the blood pressure oscillations generated by the beating of the heart. The arterial blood leaving the bulbus arteriosus under pressure flows through the gills, where respiratory gases are exchanged. Blood leaving the gills collects in a large dorsal artery, the **aorta**, which distributes blood to smaller arteries and arterioles leading to all the organs and tissues of the body. In the tissues, blood flows through beds of tiny capillaries, collects in venules and veins, and eventually returns to the sinus venosus of the heart. The unidirectional flow of blood in this circuit is enabled by one-way valves between the sinus venosus and the atrium, between the atrium and the ventricle, and between the ventricle and the bulbus arteriosus.

sinus venosus The first chamber of the heart of fish that opens into the atrium.

atrium (a' tree um) [L. *atrium*: central hall] An internal chamber. In the hearts of vertebrates, the thin-walled chamber(s) entered by blood on its way to the ventricle(s). Also, the outer ear.

ventricle A muscular heart chamber that pumps blood through the lungs or through the body.

bulbus arteriosus The last chamber of the fish heart.

aorta (a or' tah) [Gk. *aorte*: aorta] The main trunk of the arteries leading to the systemic (as opposed to the pulmonary) circulation.

Most of the pressure imparted to the blood by the contraction of the ventricle is dissipated as a result of resistance to flow in the many narrow spaces in the gill lamellae (see [Figure 48.5](#)). Therefore blood leaving the gills and entering the aorta is under low pressure, limiting the capacity of the fish circulatory system to supply the tissues with oxygen and nutrients. Yet this limitation on arterial blood pressure does not seem to limit swimming performance. Some species, such as tuna and marlin, can swim at remarkably high rates of speed for long distances.

The evolutionary transition from breathing water to breathing air had important consequences for the vertebrate circulatory system. An example of how the system changed to serve a primitive lung can be seen in the African lungfishes.

Lungfishes evolved a gas-breathing organ

Lungfishes are exposed periodically to water with low oxygen content or to situations in which their aquatic environment dries up. The adaptation that deals with these conditions is an outpocketing of the gut that serves as a lung. The lung contains many thin-walled blood vessels, so blood flowing through those vessels can pick up oxygen from air gulped into the lung.

How does the lungfish circulatory system take advantage of this new organ? In fishes, the gills are arranged on supportive gill arches (see [Figure 48.5A](#) and [B](#)). Blood flows into the gill arch in an afferent arteriole and leaves in an efferent arteriole. In lungfishes, the blood vessels in the posterior pair of gill arteries have been modified into a low-resistance conduit for blood to the lung, and a separate pulmonary vessel carries oxygenated blood from the lung back to the heart. In addition, blood from the heart flows directly into the dorsal aorta through two anterior gill arches that have lost their gill filaments. A few of the gill arches retain gill filaments, so the African lungfishes can exchange respiratory gases with either air or water.

The lungfish heart partially separates its flow of blood into pulmonary and systemic circuits; it has a partially divided atrium. The left side receives oxygenated blood from the lung, and the right side receives deoxygenated blood from the body via the sinus venosus. These two bloodstreams stay mostly separate as they flow through the ventricle and the bulbus arteriosus. As a result, oxygenated blood goes mostly to the anterior gill arteries leading to the dorsal aorta, and deoxygenated blood goes mostly to the other gill arches that have functional gill filaments. The blood leaving those posterior gill arches flows to the dorsal aorta as well as to the lung. Thus the dorsal aorta can receive oxygenated blood either from the lung (via the anterior gill arches) or from the gill filaments of the posterior gill arches.

We can conclude that the lungfish lung evolved as a means of supplementing oxygen uptake from the gills. When the water is oxygenated, the lungfish can obtain oxygen through its gills; but in oxygen-depleted water, it can depend on getting oxygen from its lung. Associated modifications of the lungfish vascular system set the stage for the evolution of separate pulmonary and systemic circulations in higher vertebrates.

Amphibians have partial separation of systemic and pulmonary circulation

In adult amphibians, a single ventricle pumps blood to the lungs and the rest of the body, but two atria receive blood returning to the heart. The left atrium receives oxygenated blood from the lungs, and the right atrium receives deoxygenated blood from the body.

Because both atria deliver blood to the same ventricle, the oxygenated and deoxygenated blood could mix, in which case blood going to the tissues would not carry a full load of oxygen. Mixing is limited, however, because anatomical features of the ventricle direct the flow of deoxygenated blood from the right atrium primarily to the pulmonary circuit and the flow of oxygenated blood from the left atrium primarily to the aorta. Partial separation of pulmonary and systemic circulation has the advantage of allowing blood destined for the tissues to sidestep the large pressure drop that occurs in the gas exchange organ. Blood leaving the amphibian heart for the tissues moves directly to the aorta, and hence to the body, at a higher pressure than if it had first flowed through the lungs as it does in the fishes.

Amphibians have another adaptation for oxygenating their blood: they can pick up a considerable amount of oxygen in blood flowing through small blood vessels in their skin.

Reptiles have exquisite control of pulmonary and systemic circulation

As described in [Chapter 32](#), the reptiles include turtles, snakes, lizards, crocodilians, and birds (see [Figures 32.21](#) and [32.22](#)). Crocodilians and birds have circulatory systems with two completely separated ventricles, creating a four-chambered heart. All other reptiles have ventricles that are not completely separated into left and right chambers.

Consider the behavior, ecology, and physiology of ectothermic reptiles (i.e., excluding birds). Many are active, powerful, fast animals, but their activity comes in bursts that are interspersed with long periods of inactivity. At these times the animals' metabolic rates are much lower than the resting metabolic rates of the endothermic birds and mammals. So enormous is the range of metabolic demand in ectothermic reptiles that they do not need to breathe continuously. Some species are accomplished divers and spend long periods under water, where they cannot breathe air.

When these animals are not breathing, it would be a waste of energy for them to pump blood through their lungs. Thus they pump blood to the lungs and the rest of the body when they are breathing, but when they are not breathing, they can bypass the pulmonary circuit and pump most of the blood to the body. How do they do this?

In ectothermic reptiles with a three-chambered heart—that is, the turtles, snakes, and lizards—the ventricle is partially divided into left and right halves by a septum. Oxygenated blood from the lungs enters the left side of the ventricle through the left atrium. Deoxygenated blood from the body enters the right side of the ventricle through the right atrium. These species have two aortas, left and right. The left aorta is positioned so that it receives oxygenated blood from the left side of the ventricle. The right aorta, however, is positioned so that it can receive blood from either the right or left side of the ventricle.

When the animal is breathing air, the resistance in the pulmonary circuit is lower than the resistance in the systemic circuit, so blood from the right side of the ventricle tends to flow into the pulmonary artery rather than the right aorta. When the animal is not breathing, pulmonary vessels constrict, resistance in the pulmonary circuit goes up, and blood from the right side of the ventricle tends to flow into the right aorta. As a result, blood from both sides of the ventricle flows through the two aortas to the systemic circuit.

Crocodylians, like birds, have two completely separated ventricles. Unlike birds, they have two aortas, one originating in each ventricle. But there is a connection between the two aortas just as they leave the heart, and this connection enables them to alter the proportions of blood going to their pulmonary and systemic circuits. When a crocodile or alligator is breathing and resistance in the pulmonary circuit is low, backpressure from the stronger left ventricle closes the valve between the right ventricle and the right aorta, forcing all of the blood from the right ventricle to flow into the pulmonary circuit. When the animal stops breathing, pulmonary vessels constrict, resistance in the pulmonary circuit rises, and pressure in the right ventricle overcomes the backpressure in the right aorta from the left ventricle. As a result, the blood from the right ventricle flows into the right aorta. This ability of all ectothermic reptiles to direct blood to their pulmonary or systemic circuits is highly adaptive for their lifestyle of intermittent breathing.

Birds and mammals have fully separated pulmonary and systemic circuits

The four-chambered hearts of birds and mammals have completely separate pulmonary and systemic circuits. Separate circuits have several advantages for these active animals with continuously high metabolic rates:

Oxygenated and deoxygenated blood cannot mix; therefore the systemic circuit always

receives blood with the highest oxygen content.

Respiratory gas exchange is maximized because the blood with the lowest oxygen content and highest CO₂ content is sent to the lungs.

Separate systemic and pulmonary circuits can operate at different pressures.

The tissues of birds and mammals have high nutrient demands and thus a very high density of blood vessels, requiring the heart to generate a high blood pressure to perfuse all the vessels of the systemic circuit. The pulmonary circuit of these animals receives a blood flow equal to that of the systemic circuit, but the lungs have far fewer blood vessels. Thus the pulmonary circuit of birds and mammals can function at lower pressures, and the four-chambered heart makes that possible.

 Activity 49.1 **Vertebrate Circulatory Systems** www.Life11e.com/ac49.1

49.2 recap

The closed circulatory system of vertebrates has evolved from a single circuit system in fishes to separate pulmonary and systemic circuits in birds and mammals. A key step was the evolution of a primitive lung in a lineage of air-breathing fishes. Further adaptations increasingly separated the flows of oxygenated and deoxygenated blood in separate circuits, as seen in amphibians and reptiles. Ectothermic reptiles retained the ability to direct blood to either the pulmonary or systemic circuit, but mammals and birds have complete division of those two circuits, allowing the circuits to function at different pressures.

learning outcomes

You should be able to:

- Understand the single circuit of the circulatory system of fishes, which are phylogenetically the earliest vertebrates.
- Describe how a lungfish can distribute oxygen to its tissues in both water and air environments.
- Explain why the circulatory system of ectothermic reptiles is unique in its control of pulmonary and systemic circulation.

- Apply knowledge about four-chambered hearts and fully separate pulmonary and systemic circulatory systems to explain the consequences of heart defects
-

1. Trace the flow of blood in circulatory system of a fish.
 2. Lungfish brooding in stagnant water can increase the oxygen content in the water immediately surrounding their eggs. How is this possible?
 3. Explain how and why ectothermic reptiles shunt blood from the pulmonary circuit when not breathing.
 4. If the ductus arteriosus in a human fetus does not close at birth, what are the consequences?
-

We will turn now to the structure and function of the mammalian heart, focusing in particular on human cardiac function.

49.3 Heart Function Depends on Properties of Cardiac Muscle

In this section we describe in detail the structure and function of the mammalian heart, using the human heart as the example. We first trace the paths of blood flow through the heart and the body, and then we examine the unique electrical properties of cardiac muscle that result in the rhythmic contractions of the heart.

focus your learning

Blood flow in mammalian hearts goes from right atrium to right ventricle to lungs and from left atrium to left ventricle to the systemic circulation. Valves prevent backflow.

In each cardiac cycle, both atria contract first, followed by both ventricles contracting, which is then followed by relaxation.

Action potentials in cardiac muscle cells depend on the properties of the ion channels in their membranes.

The mammalian heart, and therefore the human heart, has four chambers—a right and a left atrium and a right and a left ventricle ([Figure 49.2](#)). The right atrium receives blood from the systemic circuit, and the left atrium receives blood from the pulmonary circuit. The right ventricle pumps blood through the pulmonary circuit, and the left ventricle pumps blood through the systemic circuit.

(A) The human circulatory system

Vessels shown in red bring oxygenated blood from the lungs to the left side of the heart, which pumps it to the rest of the body.

Vessels shown in blue bring deoxygenated blood from the body to the right side of the heart, which pumps it to the lungs for oxygenation.

(B) The human heart

Figure 49.2 The Human Heart and Circulation (A) The major blood vessels of the body either carry blood away from the heart (arteries) or return blood to the heart (veins). **(B)** In the human heart, blood flows from right side of the heart to the lungs to the left side of the heart and then out to the body. The atrioventricular valves prevent blood from flowing back into the atria when the ventricles contract. The pulmonary and aortic valves prevent blood from flowing back into the ventricles from the arteries when the ventricles relax.

 Activity 49.2 The Human Heart www.Life11e.com/ac49.2

One-way valves between the atria and ventricles, the **atrioventricular (AV) valves**, prevent backflow of blood into the atria when the ventricles contract. The right AV valve is called the **tricuspid valve** because it has three leaves. The left AV valve is called the **bicuspid valve** because it has two leaves. The bicuspid valve is also called the **mitral valve** because it has the shape of a religious headdress called a miter. There are also one-way valves between the ventricles and the arteries leaving the heart. The **pulmonary valve** goes to the lungs, and the **aortic valve** goes to the aorta. These two valves are also called semi-lunar valves because their separate leaves are shaped like half moons.

atrioventricular (AV) valve A heart valve between an atrium and a ventricle.

tricuspid valve The right AV valve. So named because it has three leaves.

bicuspid valve The left AV valve. So named because it has two leaves.

mitral valve See bicuspid valve. So named because it has a similar shape to a miter (a

religious headdress).

pulmonary valve A one-way valve between the right ventricle of the heart and the pulmonary artery that prevents backflow of blood into the ventricle when it relaxes.

aortic valve A one-way valve between the left ventricle of the heart and the aorta that prevents backflow of blood into the ventricle when it relaxes.

Blood flows from right heart to lungs to left heart to body

The **superior** (upper) **vena cava** and the **inferior** (lower) **vena cava** (see [Figure 49.2](#)) are the large veins that return deoxygenated blood to the right atrium from the upper and lower body, respectively. The veins of the heart itself also drain into the right atrium. From the right atrium, the blood flows through the tricuspid valve into the right ventricle. The filling of the ventricle is mostly passive flow while the heart is relaxed between beats. At the end of this phase of passive ventricular filling, the atrium contracts and adds a little more blood to the ventricular volume. The right ventricle then contracts, causing the tricuspid valve to close and pumping the blood into the **pulmonary artery** leading to the lungs.

Pulmonary veins return the oxygenated blood from the lungs to the left atrium, from where the blood enters the left ventricle through the bicuspid valve. As on the right side of the heart, most left ventricular filling is passive, and is only topped off when the atria contract.

pulmonary veins Veins that return oxygenated blood from the lungs to the left atrium.

The walls of the ventricles are powerful muscles that contract around the blood with a wringing motion starting from the bottom. When pressure in the left ventricle is high enough to push open the aortic valve, blood rushes into the aorta to begin its circulation throughout the body. In [Figure 49.2](#) observe that the walls of the left ventricle are thicker than those of the right ventricle. The left ventricle has to propel blood through many more kilometers of blood vessels than does the right ventricle, and must therefore push against more resistance, even though both ventricles pump the same volume of blood.

It is the left ventricle that creates the condition of hypertrophic cardiomyopathy (HCM) that you learned about at the beginning of this chapter. Mutations that reduce the efficiency of contraction of the cardiac muscle result in the work load of the left ventricle being greater than normal, so the ventricular muscle compensates by getting bigger (hypertrophy). When the heart is repeatedly stressed by high levels of activity, as is common in athletes, the hypertrophy can become extreme ([Figure 49.3](#)). The consequences can be blockage of blood flowing into the aorta and disruption of the signals that coordinate the contractions of the ventricular muscles.

Figure 49.3 Hypertrophic Cardiomyopathy (A) Comparison of a normal and a hypertrophic heart. **(B)** Micrographs of the ventricular heart muscle fibers of a normal and a hypertrophic heart. The organization of the muscle fibers is irregular causing

inefficient contractions.

Both sides of the heart contract at the same time. Contraction of the two atria, followed by contraction of the two ventricles and then relaxation, is the **cardiac cycle**. The cardiac cycle is divided into two phases: **systole** (pronounced sís-toll-ee), when the ventricles contract, and **diastole** (die-ás-toll-ee), when the ventricles relax (**Focus: Key Figure 49.4**). At the very end of diastole (step 1 in **Figure 49.4**), just before the ventricles contract, the atria contract and top off the volume of blood in the ventricles.

cardiac cycle Contraction of the two atria of the heart, followed by contraction of the two ventricles and then relaxation.

systole (sis' tuh lee) [Gk. contraction] Contraction of a chamber of the heart, driving blood forward in the circulatory system. (Contrast with diastole.)

diastole (dye ass' toll ee) [Gk. dilation] The portion of the cardiac cycle when the heart muscle relaxes. (Contrast with systole.)

focus: key figure

(A) The filling and emptying of the ventricles

(B) Pressure and volume changes during the cardiac cycle

Figure 49.4 The Cardiac Cycle (A) The rhythmic contraction (systole) and relaxation (diastole) of the ventricles is called the cardiac cycle. (B) During diastole, the ventricles fill and pressure is low. During systole, the ventricular pressure rises and

the ventricles empty. The representation here shows pressure and volume changes for the left ventricle only. The dashed lines represent the maximum and minimum volumes of blood in the left ventricle.

Q: If these curves were for the right ventricle instead of the left ventricle, how would they differ and how would they be the same?

Animation 49.1 **The Cardiac Cycle** www.Life11e.com/a49.1

The sounds of the cardiac cycle—the “lub-dup” heard through a stethoscope—are created by the heart valves slamming shut. The closing and opening of these valves are simple mechanical events resulting from pressure differences on the two sides of the valves. As the ventricles begin to contract (step 2 in [Figure 49.4](#)), the pressure in them rises above the pressure in the atria, so the AV valves close (“lub”). When the ventricles begin to relax (step 4 in [Figure 49.4](#)), the high pressure in the aorta and pulmonary artery closes the aortic and pulmonary valves (“dup”).

Defective valves that do not close completely produce turbulent blood flow and the sounds known as heart murmurs. For example, if an AV valve does not close completely, blood will flow back into the atrium with a “whoosh” at the beginning of systole.

Blood pressure changes associated with the cardiac cycle can be measured in the large artery in your arm by using an inflatable pressure cuff and a pressure gauge, together called a sphygmo-manometer, and a stethoscope ([Figure 49.5](#)). This method measures the minimum pressure necessary to compress an artery so blood does not flow through it at all (the systolic pressure) and the maximum pressure that allows continuous flow through the artery (the diastolic pressure). A conventional blood pressure reading is expressed as the systolic pressure placed over the diastolic pressure. Healthy values for a young adult might be 120 millimeters of mercury (mm Hg) during systole and 70 mm Hg during diastole, or 120/70. Modern blood pressure measuring devices such as you might encounter in a drugstore are automated so that the stethoscope is unnecessary.

Figure 49.5 Measuring Blood Pressure Blood pressure in the major artery of the arm can be measured with a device called a sphygmomanometer, which combines an inflatable cuff and a pressure gauge. A stethoscope or an automatic sensor is used to detect sounds created by the blood vessels in response to changes in pressure during the cardiac cycle.

The heartbeat originates in the cardiac muscle

Cardiac muscle has unique adaptations that enable it to function as a pump. Cardiac muscle cells are in electrical contact with one another through gap junctions that enable action potentials to spread rapidly from cell to cell. Because a spreading action potential stimulates contraction, large groups of cardiac muscle cells contract in unison. This coordinated contraction is essential for pumping blood effectively.

Some cardiac muscle cells are **pacemaker cells** that initiate action potentials without stimulation from the nervous system. When they fire action potentials, they stimulate neighboring cells to contract. The primary pacemaker of the heart is a group of modified cardiac muscle cells, the **sinoatrial node**, located at the junction of the superior vena cava and right atrium (see [Figure 49.8](#)). The resting membrane potentials of these cells are less negative than those of other cardiac muscle cells and are not stable; instead they gradually become even less negative until they reach threshold for initiating an action potential. The action potentials of pacemaker cells are very different from those of neurons and other muscle cells (see [Figure 44.8](#)). They are slower to rise; they are broader; and they are slower to return to resting potential ([Figure 49.6A](#)). These properties of pacemaker cells are due to the ion channels in their membranes.

pacemaker cells Cardiac cells that can initiate action potentials without stimulation from the

nervous system, allowing the heart to initiate its own contractions.

sinoatrial node (sigh' no ay' tree al) [L. *sinus*: curve + *atrium*: chamber] The pacemaker of the mammalian heart.

(A) The pacemaker potential

(B) Ion channel activity of pacemaker cells

Figure 49.6

cells of the sinoatrial node. The pacemaker action potential is slow to rise and is broad. These characteristics are due to properties of Na^+ , K^+ , and two types of Ca^{2+} channels. (B) At rest, sinoatrial pacemaker cells are more permeable to Na^+ than are neurons or other muscle cells. During rest, the K^+ channels gradually close, but voltage-gated T-type Ca^{2+} channels open. When a threshold is reached, the L-type Ca^{2+} channels open, generating the action potential. Opening of the K^+ channels helps the membrane potential return to its most negative value.

Figure 49.6 The Pacemaker Potential (A) The resting potential of the pacemaker cells of the sinoatrial node gradually drifts upward between action potentials. The pacemaker action potential is slow to rise and is broad. These characteristics are due to properties of Na^+ , K^+ , and two types of Ca^{2+} channels. **(B)** At rest, sinoatrial pacemaker cells are more permeable to Na^+ than are neurons or other muscle cells. During rest, the K^+ channels gradually close, but voltage-gated T-type Ca^{2+} channels open. When a threshold is reached, the L-type Ca^{2+} channels open, generating the action potential. Opening of the K^+ channels helps the membrane potential return to its most negative value.

Pacemaker potentials involve Na^+ , Ca^{2+} , and K^+ channels (**Figure 49.6B**). As discussed in [Key Concept 44.2](#), when Na^+ or Ca^{2+} channels open, positive charges flow into the cell and the membrane potential becomes less negative. When K^+ channels open, positive charges flow out of the cell and the membrane potential becomes more negative. Because the Na^+ channels of

pacemaker cells are open more of the time than are those of other cardiac muscle cells, the pacemaker resting potential is less negative. The action potential of pacemaker cells is due to voltage-gated Ca^{2+} channels rather than voltage-gated Na^{+} channels as in neurons, skeletal muscle, and other cardiac muscle cells. These Ca^{2+} channels open and close more slowly than voltage-gated Na^{+} channels, explaining the shape of pacemaker action potentials.

The unstable resting potential of pacemaker cells is due to the behavior of cation channels. As in neurons and skeletal muscle cells, the rise of the action potential is followed by opening of voltage-gated K^{+} channels. The increased permeability of the cells to K^{+} brings the membrane potential back to a negative level. But, that restoration of a negative membrane potential causes a unique class of voltage-gated Na^{+} channels to open. At the same time, the voltage-gated K^{+} channels that restored the negative membrane potential are gradually closing. The opening Na^{+} channels and closing K^{+} channels cause the membrane potential to drift upwards (become less negative) (see [Figure 49.6B](#)).

The gradual rise in membrane potential closes the channels that allow Na^{+} to move into the cell, but as the membrane becomes less negative, some Ca^{2+} channels open, causing the membrane potential to continue its gradual rise. These Ca^{2+} channels are called T-types because they open transiently. Eventually the rising membrane potential reaches threshold for the major voltage-gated Ca^{2+} channels to open. These Ca^{2+} channels are called L-types because their opening is long-lasting. It is the opening of these L-type Ca^{2+} channels that generates the pacemaker action potential. The intricate interaction of these ion channels through their effects on membrane potential causes the rhythmic generation of action potentials that characterizes pacemaker cells.

The autonomic nervous system controls the heartbeat (speeds it up or slows it down) by influencing the rate at which the membrane potentials of pacemaker cells drift upward ([Figure 49.7](#)). Norepinephrine (NE) released onto pacemaker cells by sympathetic nerves increases the permeability of the Na^{+} channels and the Ca^{2+} channels. The result is that the resting potential of the pacemaker cells drifts up more rapidly, the interval between action potentials is decreased, and the heart beats faster. Conversely, the parasympathetic neurotransmitter acetylcholine (ACh) has opposite effects. ACh increases the permeability of K^{+} channels so that the membrane potential becomes even more negative following an action potential and rises more slowly. ACh also decreases the permeability of the Ca^{2+} channels so that the rate of rise of the membrane potential slows, the interval between pacemaker action potentials lengthens, and the heart slows down.

Figure 49.7 The Autonomic Nervous System Controls Heart Rate

Neurotransmitters from the two divisions of the autonomic nervous system either speed up (norepinephrine, NE) or slow down (acetylcholine, ACh) the rate at which the pacemaker membrane potential drifts upward, thereby controlling the rate at which pacemaker cells fire action potentials.

A conduction system coordinates the contraction of heart muscle

A normal heartbeat begins with an action potential in the sinoatrial node (**Figure 49.8**). This action potential spreads rapidly throughout the electrically coupled cells of the atria, causing them to contract in unison. Because there are no gap junctions between the cells of the atria and those of the ventricles, the action potential does not spread directly to the ventricles. Therefore the ventricles do not contract in unison with the atria.

Figure 49.8 The Heartbeat Pacemaker cells in the sinoatrial node initiate the heartbeat by firing action potentials that spread through the electrically coupled atrial muscle. The atrial action potential spreads to the atrioventricular node which, with a delay, conducts it through the bundle of His and Purkinje fibers to the cells of the ventricles.

experiment

Original Paper: Jiang, J., H. Wakimoto, J. B. Seidman and C. E. Seidman. 2013. Allele-specific silencing of mutant *Myh6* allele in mice suppresses hypertrophic cardiomyopathy. *Science* 342: 111–114.

Hypertrophic cardiomyopathy (HCM) is caused by mutations in myosin genes. A similar mutation has been engineered into mice, and they develop HCM. In addition, it was shown that treatment of these mice with cyclosporine A (CsA) exacerbates their development of HCM. Since the HCM model mice are heterozygous for the mutated gene (as are most afflicted humans), and since there are multiple myosin genes, the question arose as to whether or not the selective silencing of the mutant gene would allow the normal alleles to correct the disorganization of the cardiac muscle due to the mutant allele.

HYPOTHESES►

1. Mice genetically engineered to carry a mutation in the myosin gene most commonly responsible for HCM in humans will show the HCM phenotype, and it will be exacerbated by treatment with CsA.
2. Silencing expression of the mutant gene will prevent the development of the HCM phenotype.

METHOD

1. Using genetic engineering techniques, generate a mouse model that carries a mutation in one of its myosin genes. The heterozygotes are viable, but the homozygotes are not.
2. Using the wild type mice as a comparison, measure left ventricular wall thickness in mutant mice with and without treatment with CsA to exacerbate the development of left ventricular wall hypertrophy.
3. Develop an interference RNA (RNAi) that will silence expression of the mutant gene in vitro.
4. Transfect mice heterozygous for the mutation with the RNAi construct and at a later time assess them for hypertrophy of their left ventricular walls. Some mice are also treated with CsA, which exacerbates the development of hypertrophy in the mutant mice.
5. Calculate the means and SDs for each cohort of mice. Then do non-paired *t*-tests to see if there are significant differences.

RESULTS

Data in the graph are simulated based on reported means and standard deviations.

CONCLUSION►

The mice carrying the mutation show a significant ($P < 0.003$) increase in left ventricular wall thickness. The mutant mice treated with CsA show a larger increase in left ventricular wall thickness ($P < 0.001$) in comparison with the mutant mice not CsA treated. Thus the mutation has the expected effect of promoting the development of HCM symptoms, and the effect is exacerbated by treatment with CsA.

work with the data

The second hypothesis posed in the experiment above is that treatment of the mutant mice with interference RNA (RNAi) targeted to the mutant myosin gene will reduce the development of the HCM phenotype. The data are listed in the table. All values are for left ventricular wall thickness (mm) of individual mice and are simulated based on the reported means and SDs.

CsA treated	Not CsA treated	RNAi and CsA treated	RNAi but not CsA treated
1.60	0.96	0.87	0.63
1.34	0.98	0.82	0.68
1.50	1.01	0.87	0.85
1.39	0.89	0.91	0.65
1.50	0.86	0.74	0.68
1.44	0.91	0.83	
1.42		0.92	

QUESTIONS►

1. Comparing mutant mice that did not receive CsA, did the treatment with RNAi significantly reduce their left ventricular wall thickness?
2. Comparing mutant mice that did receive CsA, did the treatment with RNAi significantly reduce their left ventricular wall thickness?

A similar **work with the data** exercise may be assigned in LaunchPad.

How does the action potential move from the atria to the ventricles? Situated at the junction of the atria and the ventricles is a nodule of modified cardiac muscle cells—the [atrioventricular node](#)—which is stimulated by the depolarization of the atria. With a slight delay, it generates

action potentials that are conducted to the ventricles via the [bundle of His](#), which are modified cardiac muscle fibers that do not contract but do conduct action potentials. These fibers course down the septum between the left and right ventricles and divide into right and left bundle branches. The branches of conducting fibers run to the tips of the ventricles and then spread throughout the ventricular muscle mass as [Purkinje fibers](#). This system of conducting fibers ensures that the cardiac action potential spreads rapidly and evenly throughout the ventricular muscle mass, starting at the very bottom of the ventricles. The short delay in the spread of the action potential imposed by the atrioventricular node ensures that the atria contract before the ventricles do, so that the blood passes progressively from the atria to the ventricles to the arteries.

atrioventricular node A modified node of cardiac muscle that organizes the action potentials that control contraction of the ventricles.

bundle of His Fibers of modified cardiac muscle that conduct action potentials from the atria to the ventricular muscle mass.

Purkinje fibers (pur kin' jee) Specialized heart muscle cells that conduct excitation throughout the ventricular muscle.

HCM can disrupt conduction

Returning to the case of HCM introduced at the beginning of this chapter, consider in [Figure 49.8](#) how HCM can impair the function of the left ventricle. First, in many cases the septum between the ventricles is greatly modified by the hypertrophy, and this can disrupt the conducting fibers that run down through the septum. Second, the thickening of the septum near the aorta can block the entrance to the aorta and therefore impede blood flow and the emptying of the ventricle. How can these effects be prevented? In **Investigating Life: Silencing Mutant Myosin Genes** we describe a recent study on mice that have been genetically engineered to carry mutations of a gene for one of the myosin chains of cardiac muscle that is associated with a large percentage of human HCM cases. These mice develop the pathologies that are seen in humans who inherit the genes causing HCM. The investigators found that by using [*RNAI](#) to silence the mutated genes, they could prevent the development of the HCM pathology.

Electrical properties of ventricular muscles sustain heart contraction

Electrical properties of ventricular muscle fibers allow them to contract for about 300 milliseconds—much longer than skeletal muscle fibers. As in neuronal and skeletal muscle action potentials, the rising phase of the ventricular muscle cell action potentials is due to the opening of voltage-gated Na^+ channels. Unlike neurons and skeletal muscle fibers, however, ventricular muscle cells remain depolarized for a long time. This extended plateau of the action potential is due to sustained opening of voltage-gated Ca^{2+} channels ([Figure 49.9](#)). Like other muscle, cardiac muscle is stimulated to contract when Ca^{2+} is available to bind with troponin (see [Figure 47.6](#)). As long as Ca^{2+} remains in the sarcoplasm, the ventricular muscle cells continue to contract.

(A)

(B)

Figure 49.9 The Action Potential of Ventricular Muscle Fibers (A) The three phases of the action potential of ventricular muscle fibers are due to the opening and closing of voltage-gated channels. (B) At the initiation of the action potential, voltage-gated Na^+ channels open rapidly but briefly. At the same time, but more slowly, K^+ channels are closing and Ca^{2+} channels are opening. The open Ca^{2+} channels sustain the depolarization. Repolarization occurs when the Ca^{2+} channels close, and the slow opening of the K^+ channels also contributes to the repolarization.

Q: Why is the broadening of the ventricular muscle action potential important?

To terminate systole and allow the ventricles to fill again, Ca^{2+} must be rapidly cleared from

the sarcoplasm of the ventricular cells. Ca^{2+} pumps in the sarcoplasmic reticulum membrane and the cell membrane actively transport Ca^{2+} ions out of the sarcoplasm and into the sarcoplasmic reticulum or into the interstitial fluid. Thus Ca^{2+} in the sarcoplasm is maintained at a low level until the next action potential triggers another round of Ca^{2+} release and muscle contraction. The rate of cycling of Ca^{2+} into and out of the sarcoplasm puts limits on the heart rate and strength of contraction of the ventricle.

The ECG records the electrical activity of the heart

Electrical events in the cardiac muscle during the cardiac cycle are recorded by electrodes placed on the surface of the body. Such a recording is an [electrocardiogram](#), or **ECG**, or **EKG** reflecting the Greek spelling (*kardia*). The ECG is an important tool for diagnosing heart problems ([Figure 49.10A](#)).

electrocardiogram (ECG or EKG) A graphic recording of electrical potentials from the heart.

Figure 49.10 The Electrocardiogram (A) An electrocardio-gram (abbreviated as ECG or EKG) is used to monitor heart function. Electrodes attached to the person record an ECG that is amplified and displayed on a monitor. **(B)** Variations from the nor-mal pattern shown here can be used to diagnose heart problems.

Q: Abnormal ECG patterns are characteristic of HCM hearts. If there were an occasional or a long-lasting block of the AV node, what would you expect to see in the ECG?

The action potentials that sweep through the muscles of the atria and ventricles before they contract are massive, localized electrical events causing electric currents to flow throughout the body. Electrodes placed at different locations on the skin detect those currents at different times and register a voltage difference between them. The appearance of the ECG depends on the placement of the electrodes. Electrodes placed on the right wrist and left ankle produced the normal ECG shown in [Figure 49.10B](#). The wave patterns of the ECG are designated P, Q, R, S, and T, each letter representing a particular event in the cardiac muscle, as shown in the figure.

49.3 recap

The mammalian heart has two atria and two ventricles. The right atrium and ventricle serve the pulmonary circuit, and the left atrium and ventricle serve the systemic circuit. Valves that are open and shut by pressure differences prevent the backflow of blood. Modified cardiac muscle tissue in the right atrium functions to spontaneously generate pacemaker action potentials. Other modified cardiac muscle tissue between the atria and ventricles and throughout the ventricles conducts those signals and coordinates the heart contraction.

Broad action potentials in ventricular muscle reflect Ca^{2+} cycling in the ventricular muscle cells and make sustained contractions possible.

learning outcomes

You should be able to:

- Trace the path of blood through both sides of the heart, naming the major blood vessels and heart valves.
- Describe how heart valves function.
- Describe the cardiac cycle in terms of left ventricular volume and pressure, aortic pressure, and heart sounds.
- Explain how calcium ion movement into and out of the sarcoplasm of cardiac muscle cells influences the rate and strength of contraction.

-
1. Valves of the heart can become stiff and calcified, limiting the flow of blood through them in a condition called stenosis. What would be the consequences of aortic valve stenosis and of pulmonary valve stenosis?
 2. Digitalis is a drug that causes an increase in Ca^{2+} concentration in the cardiac muscle cells. Why is it used to treat patients with a weakened heart?
 3. Heart valve stenosis impedes blood flow, whereas heart valve prolapse allows blood to flow backward (regurgitation). Both of these conditions can be detected as heart murmurs when a stethoscope is used to listen to heart sounds. When in the cardiac cycle could a heart murmur indicate aortic valve stenosis, and when could it indicate aortic valve prolapse? Explain your answer.

Next we will consider the composition of the blood and the characteristics of the vessels through which blood circulates around the body, illustrating once again how structure serves function. We will also consider the role of the lymphatic vessels that return interstitial fluid to the blood.

***connect the concepts** The use of RNAi to block gene expression at the mRNA level is discussed in [Key Concept 18.4](#).

49.4 Circulatory System Functions Depend on Blood and Blood Vessels

Blood is a connective tissue, and like all connective tissues, it consists of cells suspended in an extracellular matrix. There are a variety of blood cell types with different functions, and the extracellular matrix has a complex composition that is highly regulated. The unusual feature of blood is that the extracellular matrix is a liquid, so blood is a fluid tissue that circulates in a system of closed vessels through the bodies of vertebrates and invertebrates that have closed circulatory systems. The properties of the different classes of vessels reflect their functions.

focus your learning

Red blood cells are generated in bone marrow and, until they are destroyed in the spleen, they transport respiratory gases.

Platelets and blood proteins are responsible for blood clotting.

Smooth muscle cells in arteries and arterioles control blood flow to specific tissues and also control blood pressure.

Extracellular fluid exchange between the blood and the interstitial space occurs in capillary beds and depends on hydrostatic pressure pushing water out of the capillaries and osmotic pressure pulling water back into the capillaries.

One-way valves and muscle contraction help return venous blood to the heart.

The cells of the blood can be separated from the fluid matrix, called blood plasma, by centrifugation ([Figure 49.11](#)). If a sample of blood is spun in a centrifuge, all the cells move to the bottom of the tube, leaving the clear, straw-colored blood plasma on top. The packed cell volume, or hematocrit, is the percentage of the blood volume made up by red blood cells (RBCs). Normal hematocrit is about 42 percent for women and 46 percent for men, but these values can vary considerably. They are usually higher, for example, in people who live and work at high elevations, because their exposure to low oxygen stimulates the production of more RBCs. Between the blood plasma and the packed RBCs there is a very thin layer—less than 1 percent of the blood volume—called the buffy coat that contains most of the white blood cells and platelets. [Platelets](#) are pinched-off fragments of a class of bone marrow cells. Here we consider the RBCs and the platelets. White blood cells, or leukocytes, are cells of the immune system, discussed in [Chapter 41](#).

platelet A membrane-bounded body without a nucleus, arising as a fragment of a cell in the bone marrow of mammals. Important to blood-clotting action.

Figure 49.11 The Composition of Blood Blood consists of a complex aqueous solution (the blood plasma) and numerous cell types and cell fragments. The hematocrit (arrow) is a measure of the volume of RBCs as a percentage of total blood volume. At the surface of the packed cells is the thin buffy coat that contains leukocytes and platelets.

Red blood cells transport respiratory gases

As is obvious from the hematocrit, most blood cells are RBCs—also called [erythrocytes](#). Mature RBCs are biconcave, flexible discs that lack nuclei but are packed with hemoglobin. Their function is to transport respiratory gases (see [Key Concept 48.4](#)). The shape of RBCs gives them a large surface area for gas exchange, and their flexibility enables them to squeeze through narrow capillaries. Men have 4.5–6.0 million red blood cells per microliter of blood, and women have 3.5–5.0 million.

erythrocyte (ur rith' row site) [Gk. *erythros*: red + *kytos*: container] A red blood cell.

RBCs, as well as all the other cellular components of blood, are generated by stem cells in the bone marrow, particularly in the ribs, breastbone, pelvis, vertebrae, and the long bones of the limbs. RBC production is controlled by a hormone, [erythropoietin \(EPO\)](#), released by cells in the kidneys in response to insufficient oxygen—[hypoxia](#). Many tissues respond to hypoxia by expressing a transcription factor called hypoxia-inducible factor 1 (HIF-1). When the kidneys become hypoxic and express HIF-1, one of the actions of the transcription factor is to activate the gene encoding erythropoietin. Increased circulating erythropoietin extends the lives of mature RBCs and stimulates production of new RBCs in the bone marrow.

erythropoietin (EPO) (ur rith' row poi' i tn) A hormone produced by the kidney in response to lack of oxygen that stimulates the production of red blood cells.

hypoxia A deficiency of oxygen.

Under normal conditions, your bone marrow produces about 2 million RBCs every second.

Developing RBCs divide many times while still in the bone marrow, and during this time they produce hemoglobin. When hemoglobin makes up about 25 percent of the volume of the immature RBC, the nucleus is extruded from the cell and other cell organelles are also lost. This process is almost complete when the newly mature RBC squeezes between the endothelial cells of blood vessels in the bone marrow and enters the circulation. Loss of nuclei from the RBCs occurs in most mammalian species, but the RBCs of a few mammals and of all other vertebrates are nucleated.

Each RBC circulates for about 120 days. As it gets older, its membrane becomes less flexible and more fragile, so older RBCs are more likely to rupture as they bend to fit through narrow capillaries.

RBCs are particularly squeezed in the [spleen](#), an organ that sits near the stomach in the upper left side of the abdominal cavity. The spleen has many sinuses (cavities) that serve as reservoirs for RBCs. To get into the sinuses, however, the RBCs must squeeze between spleen cells. When old RBCs are ruptured by this squeezing, their remnants are taken up and degraded by macrophages (a class of white blood cells that ingest debris and foreign materials; see [Key Concept 41.3](#)).

spleen Organ that serves as a reservoir for venous blood and eliminates old, damaged red blood cells from the circulation.

Platelets are essential for blood clotting

Besides producing erythrocytes and leukocytes, the bone marrow stem cells described in [Key Concept 41.1](#) also produce cells called [megakaryocytes](#). Megakaryocytes are large cells that remain in the bone marrow and release platelets into the circulation. A platelet is a tiny fragment of a cell without cell organelles, but it is packed with enzymes and chemicals necessary for its function: sealing leaks in blood vessels and initiating [blood clotting](#) ([Figure 49.12](#)).

megakaryocytes A bone marrow cell that produces blood platelets.

blood clotting A cascade of events involving platelets and circulating proteins (clotting factors) that seals damaged blood vessels.

Figure 49.12 Blood Clotting (A) Damage to a blood vessel initiates a cascade of events that produce a fibrin meshwork. **(B)** As the meshwork forms, red blood cells are enmeshed in the fibrin threads, forming a clot, as shown in this color-enhanced electron micrograph.

Damage to a blood vessel exposes collagen fibers. An encounter with collagen fibers activates platelets. The platelet swells, becomes irregularly shaped and sticky, and releases chemicals that activate other platelets and initiate the clotting of blood. The sticky platelets also form a plug at the damaged site.

Blood clotting requires many steps and many clotting factors, most of which are circulating in the blood in an inactive form. The absence of any one of these proteins can impair clotting, resulting in excessive bleeding. Because the liver produces most of the clotting factors, liver diseases such as hepatitis and cirrhosis can result in excessive bleeding. People with hemophilia experience uncontrolled bleeding because of a genetic inability to produce a clotting factor.

Blood clotting factors participate in a cascade of chemical activations of other substances circulating in the blood. The cascade begins with damage to a blood vessel or other tissue that exposes the blood to proteins such as collagen that are normally separated from the blood by endothelial cells lining the blood vessels. This exposure activates platelets and begins the clotting factor cascade. The end result of this cascade is to convert an inactive circulating enzyme, **prothrombin**, to its active form, **thrombin**. Thrombin cleaves molecules of **fibrinogen**, a plasma protein, forming insoluble threads of **fibrin**. The fibrin threads form the meshwork that binds platelets, seals the vessel, and provides a scaffold for the formation of scar tissue (see [Figure 49.12](#)).

prothrombin The inactive form of thrombin, an enzyme involved in blood clotting.

thrombin An enzyme involved in blood clotting; cleaves fibrinogen to form fibrin.

fibrinogen A circulating protein that can be stimulated to fall out of solution and provide the structure for a blood clot.

fibrin A protein that polymerizes to form long threads that provide structure to a blood clot.

Arteries withstand high pressure, arterioles control blood flow

The walls of the large arteries have many extracellular collagen and elastin fibers that enable them to withstand the high blood pressures generated by the heart (**Figure 49.13A**). These elastic tissues have another important function: as you saw with the bulbus arteriosus in fish, they are stretched during systole, and thereby store some of the energy imparted to the blood by the heart. Elastic recoil during diastole returns this energy to the blood by squeezing it and pushing it forward. As a result, even though pressure in the arteries pulsates with the beating of the heart, the flow of blood is smoother than it would be through a system of rigid pipes.

Figure 49.13 Anatomy of Blood Vessels (A) The different anatomical characteristics of arteries and veins match their functions. (B) Blood from the arterial system feeds into capillary beds where exchanges with the interstitial fluid occur. The venous system returns the blood to the heart. (C) The cross-sectional area encompassed by each vessel type is graphed along with the pressure and velocity of the blood within it.

Activity 49.3 Structure of Blood Vessels www.Life11e.com/ac49.3

Contraction of smooth muscle cells in the walls of the arteries constricts the vessels, and relaxation of the smooth muscle dilates them. When the diameter of a vessel changes, its resistance to blood flow changes, and the amount of blood flowing through it changes as a result. Neural and hormonal mechanisms act on smooth muscle cells in the walls of the arteries and arterioles, controlling the flow of blood through these vessels. The arterioles are referred to as resistance vessels because their resistance can vary to control the blood flow to specific tissues.

Materials are exchanged in capillary beds by filtration, osmosis, and diffusion

Beds of capillaries lie between arterioles and venules ([Figure 49.13B](#)). Most cells are not more than a few cell diameters away from a capillary. The needs of cells are served by the exchange of materials between blood and interstitial fluid across the capillary walls. Capillary walls are thin and permeable to water and many solutes. Also, blood flows slowly through capillaries, allowing time for exchange.

It may seem strange that blood flows through the large arteries rapidly at high pressures, but when it reaches the small capillaries the pressure and rate of flow decrease ([Figure 49.13C](#)). When you constrict the opening of a garden hose, the pressure in the hose and the velocity of the water spraying out increase. But keep in mind that the arteries branch into many arterioles that serve huge numbers of capillaries. Even though each capillary has a diameter so small that red blood cells pass through in single file, there are so many capillaries that their total crosssectional area is much greater than that of any other class of vessel. As a result, all the capillaries together have a much greater capacity for blood than do the arterioles.

Capillary walls consist of a single layer of endothelial cells ([Figure 49.14](#)). Capillaries are permeable to water, some ions, and some small molecules but not to large molecules such as proteins, and certainly not to red blood cells. At the arterial (high pressure) end, blood pressure squeezes water and small solutes out through spaces between the cells of the capillary walls into the surrounding intercellular space.

Figure 49.14 A Narrow Lane Capillaries have a very small diameter, and blood flows through them slowly.

Media Clip 49.1 **Capillary Flow: A Tight Squeeze** www.Life11e.com/mc49.1

Why don't water and small-molecular-weight solutes collect in the intercellular spaces? How is the blood volume maintained if fluid is continuously leaking out of the capillaries? An answer to such questions was put forth more than 100 years ago by the physiologist E. H. Starling. Starling suggested that water movement across capillary walls is a result of two opposing forces, which are now known as **Starling's forces**:

Starling's forces The two opposing forces responsible for water movement across capillary walls: blood pressure, which squeezes water and small solutes out of the capillaries, and osmotic pressure, which pulls water back into the capillaries.

. Blood hydrostatic pressure squeezes water and small solutes out of the capillaries.

. Blood osmotic pressure pulls water back into the capillaries.

Blood hydrostatic pressure is high at the arterial end of a capillary bed and steadily drops as blood moves toward the venous end (**Figure 49.15**). Blood osmotic pressure is due to the large protein molecules that cannot leave the capillaries, and it is relatively constant along the capillaries. As long as the blood hydrostatic pressure is above the blood osmotic pressure, fluid leaves the capillaries. At the venule end of most capillaries, blood hydrostatic pressure falls below blood osmotic pressure, so fluid returns to the capillaries. The actual numbers for a normal capillary bed in a resting person suggest that there would be a *slight* net loss of fluid to the intercellular spaces. This loss, about 4 liters per day, percolates between cells as the interstitial fluid before it returns to the venous blood via the **lymphatic system**, which we will discuss later in this chapter.

Figure 49.15 Starling's Forces Starling's model explains fluid balance in capillary beds. **(A)** When blood hydrostatic pressure is greater than blood osmotic pressure, fluid leaves the capillaries; when blood hydrostatic pressure falls below blood osmotic pressure, fluid returns to the capillaries. **(B)** The balance of these two forces changes over the capillary bed as blood hydrostatic pressure falls.

Recent research suggests that in addition to large protein molecules in the blood, bicarbonate

ions (HCO_3^-) may also contribute significantly to pulling water back into the capillaries. The CO_2 produced by cellular metabolism diffuses into the endothelial cells lining the capillaries, where it is converted into HCO_3^- and released into the plasma. When an individual is at rest, the increasing HCO_3^- concentration can cause the blood osmotic pressure at the venous end to be 30 mm Hg higher than at the arterial end, and during strenuous exercise this difference can be much higher. Thus it appears that CO_2 and HCO_3^- are major factors that pull water back into the capillaries.

All capillaries are permeable to O_2 , CO_2 , and small ions. Lipid-soluble substances readily pass through the capillary walls. Water and small solutes pass through intercellular spaces in the capillary wall, and through holes called **fenestrations** in the endothelial cells. More permeable and less selective capillaries are found in the digestive tract, where nutrients are absorbed, and in the kidneys, where wastes are filtered. Capillary endothelial cells also contain transporters that can facilitate the passage of specific molecules, such as glucose and lactate. Overall, permeability varies widely in different capillary beds—an important consideration in the design and delivery of drugs.

fenestrations Small holes in the walls of some capillaries.
--

The capillaries of the brain are a special case, being rather impermeable and wrapped by glia. Not much can pass through them other than lipid-soluble substances (including alcohol and anesthetics). This high selectivity of brain capillaries is known as the **blood-brain barrier**. Even in the brain, however, there are specific regions where the capillaries are more permeable, enabling the brain to detect non-lipid-soluble hormones.

Blood flows back to the heart through veins

The pressure of the blood flowing from capillaries to venules is low and insufficient to propel blood back to the heart. The walls of veins are more expandable than the walls of arteries, and blood tends to accumulate in veins. As much as 60 percent of your total blood volume may be in your veins when you are resting. Because of their high capacity to stretch and store blood, veins are called capacitance vessels.

Blood flow through veins that are above the level of the heart is assisted by gravity. Below the level of the heart, however, venous return is against gravity. The most important force propelling blood from these regions is the squeezing of the veins by the contractions of surrounding skeletal muscles. As muscles contract, the veins are compressed and blood is squeezed through them. Blood flow may be temporarily obstructed during a prolonged muscle contraction, but when muscles relax, blood is free to move again. One-way valves in the veins of the extremities prevent backflow of blood. Thus whenever a vein is squeezed, blood is propelled forward toward the heart (**Figure 49.16**).

Figure 49.16 One-Way Flow Veins of the extremities have valves that prevent blood from flowing backward, and contractions of skeletal muscle help move blood toward the heart.

In a resting person, gravity causes blood accumulation in the veins of the lower body and exerts backpressure on the capillary beds. This backpressure shifts the balance between blood hydrostatic pressure and osmotic pressure, causing increased loss of fluid to the intercellular spaces. That is why your feet swell during a long airline flight.

Because of the one-way valves in the veins of the legs, the contractions of leg muscles act as auxiliary vascular pumps when an animal walks or runs and facilitate the return of blood to the heart from the lower body. As a greater volume of blood is returned to the heart, the heart contracts more forcefully and its pumping action is enhanced. The heartbeat gets stronger because of a property of cardiac muscle cells described by the [Frank-Starling law](#): if the cardiac muscle cells are stretched, as they are when the volume of returning blood increases, they contract more forcefully.

Frank–Starling law The principle that the stroke volume of the heart increases with increased return of blood to the heart.

The actions of breathing also help return venous blood to the heart. The muscles involved in inhalation create negative pressure that pulls air into the lungs (see [Figure 48.11](#)), and this negative pressure also pulls blood toward the chest, increasing venous return to the right atrium. In addition, some of the largest veins closest to the heart contain smooth muscle that contracts at the onset of exercise. Contraction of veins can rapidly increase venous return and stimulate the heart in accord with the Frank-Starling law, increasing cardiac output.

Lymphatic vessels return interstitial fluid to the blood

The interstitial fluid contains water and other small molecules, but no RBCs, and less protein than found in plasma. A separate system of vessels—the ***lymphatic system**—returns interstitial fluid to the blood. Each capillary bed contains at least one blind-ended lymph capillary.

Interstitial fluid that enters the lymphatic vessels is called **lymph**. Fine lymphatic capillaries merge into progressively larger vessels and ultimately into the right and the left **lymphatic ducts**—that empty into large veins at the base of the neck (see [Figure 41.2](#)). The left lymphatic duct, also known as the **thoracic duct**, carries most of the lymph from the lower part of the body and is larger than the right lymphatic duct. Lymphatic vessels, like veins, have one-way valves that keep the lymph flowing toward the lymphatic ducts. Therefore lymph, like blood, is propelled toward the heart by skeletal muscle contractions and breathing movements. **Lymph nodes** along the major lymphatic vessels are a major site of lymphocyte production and of the phagocytic action that removes microorganisms and other foreign materials from the circulation.

lymph [L. *lympa*: liquid] A fluid derived from blood and other tissues that accumulates in intercellular spaces throughout the body and is returned to the blood by the lymphatic system.

lymphatic duct One of two large lymphatic vessels that drains lymph into a subclavian vein.

thoracic duct The connection between the lymphatic system and the circulatory system.

lymph node A specialized structure in the vessels of the lymphatic system. Lymph nodes contain lymphocytes, which encounter and respond to foreign cells and molecules in the lymph as it passes through the vessels.

Vascular disease is a killer

As mentioned at the beginning of this chapter, cardiovascular disease is responsible for about one-fourth of all deaths each year in the United States, and the same is true in Europe. The immediate cause of most of these deaths is not a defect in heart muscle as in cases of HCM, but is heart attack or stroke—both of which are usually the result of a disease called **arteriosclerosis** (“hardening of the arteries”) that begins many years before symptoms are detected.

Healthy arteries have a smooth internal lining of endothelial cells ([Figure 49.17A](#)) that can be damaged by chronic high blood pressure, smoking, a high-fat diet, or microorganisms. Deposits called **plaque** begin to form at sites of endothelial damage, initiating an early stage of arteriosclerosis called **atherosclerosis**. First, the damaged endothelial cells attract certain white blood cells to the site. These cells are then joined by smooth muscle cells migrating from the deeper layers of the arterial wall. Lipids, especially cholesterol, are deposited in these cells, so that the developing plaque becomes fatty. Fibrous connective tissue made by the invading smooth muscle cells in the plaque, along with deposits of calcium, gradually make the artery wall less elastic—hence “hardening of the arteries.” Plaque deposits narrow the artery and causes turbulence in the blood flow. Blood platelets stick to the plaque (see [Figure 49.12](#)) and initiate formation of an intravascular blood clot, a **thrombus** that can block the artery ([Figure 49.17B](#)).

(A) Healthy

(B) Atherosclerotic

Figure 49.17 Atherosclerotic Plaque (A) A healthy, clear artery. **(B)** An atherosclerotic artery, clogged with plaque and a thrombus.

plaque (plack) [Fr. a metal plate or coin] (1) A circular clearing in a layer (lawn) of bacteria growing on the surface of a nutrient agar gel. (2) An accumulation of prokaryotic organisms on tooth enamel. Acids produced by these microorganisms cause tooth decay. (3) A region of arterial wall invaded by fibroblasts and fatty deposits.

atherosclerosis (ath' er oh sklair oh' sis) [Gk. *athero*: gruel, porridge + *skleros*: hard] A disease of the lining of the arteries characterized by fatty, cholesterol-rich deposits in the walls of the arteries. When fibroblasts infiltrate these deposits and calcium precipitates in them, the disease becomes **arteriosclerosis**, or "hardening of the arteries."

thrombus (throm' bus) [Gk. *thrombos*: clot] A blood clot that forms within a blood vessel and remains attached to the wall of the vessel. (Contrast with embolus.)

The blood supply to the heart muscle flows through the [coronary arteries](#), which are highly susceptible to atherosclerosis. As these arteries narrow, blood flow to the heart muscle decreases, causing the symptoms of chest pain and shortness of breath during mild exertion. A person with atherosclerosis is at high risk of forming a thrombus in a coronary artery. This condition, called [coronary thrombosis](#), can totally block the vessel, causing a [myocardial infarction](#) (heart attack).

coronary artery An artery that serves the cardiac muscles.

coronary thrombosis A blood clot in a blood vessel of the heart.

myocardial infarction (MI) Blockage of an artery that carries blood to the heart muscle; a “heart attack.”

A piece of a thrombus that breaks loose, called an **embolus**, is likely to travel to and become lodged in a vessel of smaller diameter, blocking its flow (an **embolism**). Arteries already narrowed by plaque formation are likely places for an embolism. An embolism in an artery in the brain causes the cells fed by that artery to die. This event is a **stroke**. The specific damage resulting from a stroke, such as memory loss, speech impairment, or paralysis, depends on the location of the blocked artery in the brain.

embolus (em' buh lus) [Gk. *embolos*: stopper] A circulating blood clot. Blockage of a blood vessel by an embolus or a bubble of gas is called an **embolism**. (Contrast with thrombus.)

stroke An embolism in an artery in the brain that causes the cells fed by that artery to die. The specific damage, such as memory loss, speech impairment, or paralysis, depends on the location of the blocked artery.

Important risk factors for developing atherosclerosis are your genetic predisposition and your age. Environmental risk factors also play a large role, however. These include high-fat and high-cholesterol diets, smoking, and a sedentary lifestyle. Certain untreated medical conditions such as hypertension (high blood pressure), obesity, and diabetes are also risk factors for atherosclerosis. For those who have a genetic predisposition to atherosclerosis, it is even more important to minimize environmental risk factors. Changes in diet and behavior and treatment of predisposing medical conditions can prevent and reverse early atherosclerosis and help fend off this silent killer.

49.4 recap

Blood is a fluid tissue with cellular components that play roles in transport of respiratory gases, immune system function, and blood clotting. The properties of the arteries, arterioles, capillaries, venules, and veins reflect their functions. Exchanges between the blood and interstitial fluids occur in the smallest of those vessels, the capillaries. These exchanges are governed by Starling's forces and the movement of HCO_3^- into the blood. Lymphatic vessels return interstitial fluid to the blood.

learning outcomes

You should be able to:

- Describe the features, life cycle, and function of a red blood cell.
- Describe the blood clotting process.
- Explain the role of arterioles in the control of blood flow.
- Explain the forces that cause water to leave and reenter the capillaries.
- Describe the factors that affect the return of blood in veins to the heart.

- [1.](#) Why do athletes train at high altitudes?
- [2.](#) Why is the blood clotting process called a cascade?
- [3.](#) Why are arterioles called resistance vessels and veins called capacitance vessels, and what do these terms imply about function?
- [4.](#) In advanced starvation, the body breaks down its blood plasma proteins for energy. At this stage of disease, fluid accumulates in the abdomen and the extremities. What is the connection between these two consequences of starvation?

Every tissue in the body requires an adequate flow of oxygen-saturated blood. Blood flow depends on the maintenance of an appropriate blood pressure, and the distribution of blood flow throughout the body depends on control of the resistance in the blood vessels supplying different tissues.?

***connect the concepts** The lymphatic system is introduced in conjunction with the immune system. See [Key Concept 41.1](#).

49.5 The Circulation Is Controlled by Hormonal and Neural Signals

When we investigate how a physiological process is regulated, we start by identifying the critical components of that process, how they can be controlled, and the information used to govern that control. Because blood flow depends on pressure, we can identify the mean arterial pressure as a critical variable of the circulatory system.

focus your learning

Local blood flow is controlled to meet local metabolic need by autoregulatory responses of arteriole smooth muscles.

Mean arterial pressure is regulated through neural and hormonal control of smooth muscles in arterioles.

Baroreceptors in the walls of large arteries continuously convey blood pressure information to the cardiovascular regulatory center in the brain, which controls the neural and hormonal mechanisms that influence mean arterial pressure.

Pressure in the aorta oscillates between systole and diastole, and the duration of diastole is usually twice as long as that of systole (see [Figure 49.4](#)). Therefore a simple way of estimating the mean arterial pressure (MAP) is to take the diastolic pressure and add to it one-third of the difference between systolic and diastolic pressure. However, to understand the physiological mechanisms that control MAP, we have to consider the factors that determine it. MAP is determined by the cardiac output (CO) and the resistance to flow in the blood vessels, or total peripheral resistance (TPR):

$$\text{MAP} = \text{CO} \times \text{TPR}$$

Since CO is equal to the heart rate (HR) times how much blood the heart pumps with each beat (stroke volume [SV]), the critical relationships can be expressed as:

$$\text{MAP} = \text{HR} \times \text{SV} \times \text{TPR}$$

HR, SV, and TPR are controlled by neural and hormonal mechanisms at both the local and systemic levels.

At the local level, each tissue controls its own blood flow through [autoregulatory mechanisms](#) that alter the diameter and therefore the resistance of the arterioles serving it. The collective autoregulatory actions in the arterioles in all tissues of the body influence TPR and therefore MAP. If many arterioles suddenly dilate, TPR goes down and MAP falls. If many arterioles constrict, TPR goes up and MAP goes up. Therefore changes in MAP provide information about changing needs of the body. In addition, as blood flows through capillary beds, its composition changes—its CO₂ content goes up and its O₂ content goes down. Thus blood composition also provides information the body uses to regulate the circulatory system.

autoregulatory mechanisms In mammalian circulatory systems, local control of blood flow through capillary beds by constriction or dilation of incoming arterioles in response to local metabolite concentrations.

The nervous and endocrine systems respond to changes in MAP and blood composition by changing breathing rate, heart rate, stroke volume, and peripheral resistance to match the metabolic needs of the body.

Activity 49.4 **Blood Pressure and Heart Rate Simulation** www.Life11e.com/ac49.4

Autoregulation matches local blood flow to local need

The amount of blood that flows through a capillary bed is controlled by the smooth muscle of the arteries and arterioles feeding that bed. **Figure 49.18** illustrates the flow of blood in a typical capillary bed. Blood flows into the bed from an arteriole. Smooth muscle “cuffs,” or **precapillary sphincters**, on the arteriole can shut off the supply of blood to the capillary bed. When the precapillary sphincters are relaxed and the arteriole is open, blood flow through the capillaries increases.

Figure 49.18 Local Control of Blood Flow Low O₂ concentrations or high levels of metabolic by-products cause the smooth muscle of the arteries and arterioles to relax, thus increasing the supply of blood to the capillary bed.

precapillary sphincter A cuff of smooth muscle that can shut off the blood flow to a capillary bed.

Autoregulation depends on the sensitivity of the smooth muscle to its local chemical environment. Low O₂ concentrations and high CO₂ concentrations cause the smooth muscle to relax, thus increasing the supply of blood, which brings in more O₂ and carries away CO₂—a response known as hyperemia, which means “excess blood.” Increases in other by-products of metabolism, such as lactic acid, hydrogen ions, potassium, and adenosine (all of which increase

in exercising muscle), also promote hyperemia. Hence activities that increase the metabolism of a tissue also induce hyperemia in that tissue.

Arterial pressure is regulated by hormonal and neural mechanisms

Control and regulation of the circulatory system begins with the local autoregulatory mechanisms that alter the resistance of arteries and arterioles feeding capillary beds. The demands of the capillary beds influence MAP and blood composition. Both of these provide information for the control of endocrine and neural responses that act to return blood pressure and composition to normal. Thus circulatory functions are matched to the regional and overall needs of the body.

Arteries and arterioles are innervated by the autonomic nervous system, particularly the sympathetic division. The sympathetic postganglionic neurotransmitter norepinephrine binds to receptors in smooth muscle in blood vessels in the gut and other tissues not essential for “fight or flight” and causes these vessels to constrict, resulting in reduced blood flow through them and an elevation in MAP. As we discussed earlier in this chapter, increased sympathetic activity increases heart rate, and by increasing the strength of the cardiac muscle contraction, it also increases stroke volume.

Hormones also play a role in regulating arterial pressure. Epinephrine has actions similar to those of norepinephrine and is released from the adrenal medulla during massive sympathetic activation stimulated by a fall in arterial pressure or by activation of the fight-or-flight response to a dangerous threat. Another hormone, [angiotensin](#), is produced when blood pressure in the kidneys falls ([Figure 49.19](#)). These hormones influence arterioles located in peripheral tissues (extremities) or in tissues whose functions need not be maintained continuously (such as the digestive system). By reducing blood flow in those arterioles, the hormones increase central blood pressure and blood flow to essential organs such as the heart, brain, and kidneys.

angiotensin (an' jee oh ten' sin) A peptide hormone that raises blood pressure by causing peripheral vessels to constrict. Also maintains glomerular filtration by constricting efferent vessels and stimulates thirst and the release of aldosterone.

Figure 49.19 Control of Blood Pressure through Local and Systemic Mechanisms A drop in arterial pressure reduces blood flow to tissues, resulting in local accumulation of metabolic wastes. This change in the extracellular environment stimulates autoregulatory opening of the arterioles. A fall in central blood pressure is prevented by negative feedback mechanisms (including the release of antidiuretic hormone, ADH) that constrict arterioles in less essential tissues and stimulate maintenance of blood volume and blood pressure.

The autonomic nervous system activity that controls heart rate and constriction of blood vessels originates in a cardiovascular control center in the medulla. Many inputs converge on this central integrative network and influence the commands it issues via parasympathetic and sympathetic nerves ([Figure 49.20](#)). Of special importance is incoming information about changes in blood pressure from [baroreceptors](#) (stretch receptors) in the walls of the large arteries leading to the brain—the aorta and the carotid arteries.

Figure 49.20 Regulating Cardiac Output The autonomic nervous system controls heart rate in response to information about blood pressure and blood composition originating in baroreceptors and chemoreceptors shown at the bottom of the figure. Information from these sensors goes to the cardiovascular control center in the medulla, where it is integrated with other information. The medullary center generates responses in the sympathetic and parasympathetic nervous systems that control cardiac output.

baroreceptor [Gk. *baros*: weight] A pressure-sensing cell or organ. Sometimes called a stress receptor.

Increased activity in baroreceptors of the large arteries signals rising blood pressure and inhibits sympathetic nervous system signaling to arteries and arterioles while increasing parasympathetic signaling to the heart's pacemaker. As a result, the heart slows and arterioles in peripheral tissues dilate, reducing blood pressure. If pressure in the large arteries falls, the activity of the baroreceptors decreases, stimulating sympathetic output to the arteries and arterioles while reducing parasympathetic output to the heart's pacemaker. As a result, the heart beats faster and the arterioles in peripheral tissues constrict, increasing blood pressure.

Another hormone that helps stabilize blood pressure is [antidiuretic hormone \(ADH\)](#), also called [vasopressin](#), which is secreted by the posterior pituitary in response to a fall in the activity of the baroreceptors, signaling a fall in arterial pressure. ADH causes the kidneys to reabsorb more water and thereby maintain blood volume and increase blood pressure (see [Figure 51.14](#)). Increased activity of the baroreceptors inhibits the release of ADH, and as a result the kidneys excrete more water, reducing blood volume and contributing to a fall in arterial pressure (see [Figure 49.19](#)).

antidiuretic hormone (ADH) See vasopressin.

ADH See vasopressin.

vasopressin A hormone that promotes water reabsorption by the kidney. Produced by neurons in the hypothalamus and released from nerve terminals in the posterior pituitary. Also called antidiuretic hormone or ADH.

Other information that causes the cardiovascular control center to increase heart rate and blood pressure comes from [*chemore-ceptors](#) in the medulla, aorta, and the carotid arteries.

49.5 recap

The delivery of blood to tissues is controlled locally by autoregulatory mechanisms that dilate or constrict arterioles. These local actions are translated into alterations in central blood pressure and composition that are detected by neural and hormonal mechanisms, which then mediate corrective cardiovascular adjustments.

learning outcomes

You should be able to:

- Describe mechanisms underlying autoregulation of local blood flow.
- Describe the role of the autonomic nervous system in regulating MAP.
- Draw a diagram showing how an increase or a decrease in the firing rate of baroreceptors causes a change in MAP.
- Apply knowledge about local and systemic controls of cardiovascular functions to describe interactions between the two.

1. Why is autoregulation in [Figure 49.19](#) described as a positive feedback loop?
2. Distinguish between the roles of the two divisions of the autonomic nervous system (ANS) in regulating MAP?
3. Baroreceptor neurons have a range of firing rates depending on their degree of stretch, and at rest they are firing at the midpoint of that range. Why is this adaptive?

investigatinglife

QA Are there potential therapies that could treat HCM?

Any organ of your body can shut down for a while and you can re-cover—with one exception, your heart. Cardiac arrest lasting only minutes can result in death. But why should the heart of a healthy, physically fit, top-performing athlete stop? Just as physical conditioning results in making skeletal muscles bigger and stronger, it does the same for the heart. The heart responds to increased demand by getting bigger and stronger. However, if an individual has a large number of mutations in genes responsible for proteins involved in contractions of cardiac muscle, that muscle will be less efficient. To compensate for that inefficiency, the heart gets even bigger than a normal heart would when repeatedly challenged by excessive exercise. Especially in the walls of the left ventricle, hypertrophy can have two serious consequences: (1) The opening of the aorta is at the top of the heart next to the septum that divides the two ventricles. Enlargement of that septum can block the entrance to the aorta, so the cardiac output falls. (2) The bundle of His and the left and right bundle branches that convey the pacemaker potential to the ventricular muscle course down through the septum. Hypertrophy of the septum can interfere with conduction of these critical signals. If advanced conditions of HCM are discovered, there are surgical procedures that remove some of the heart muscle.

Future directions

The mutations responsible for the development of HCM are not rare, but most people who carry them live their entire lives without even knowing they are at risk for HCM. Why? Most people do not place the excessive demands on their hearts that athletes do. So what can be done to reduce the risk of death by HCM? Preventative measures such as genetic screening could allow carriers of the mutations to make decisions about whether or not to pursue extreme physical activity. Physical examinations including ECGs, sonograms, and even magnetic resonance imaging (MRI) would enable diagnosis and recommendations to decrease levels of physical exertion. The work presented in Investigating Life: Silencing Mutant Myosin Genes suggests a potential future treatment through gene therapy. If safe reagents could be developed to silence the mutant genes, and those reagents were applied before severe HCM developed, they could have a protective benefit.

► 49.1 Circulatory Systems Serve Many Functions

- The metabolic needs of the cells of many small animals are met by direct exchange of materials with the external medium. The metabolic needs of the cells of larger animals are met by a **circulatory system** that transports nutrients, respiratory gases, and metabolic wastes throughout the body.

circulatory system A physiological system consisting of a muscular pump (heart), a fluid (blood or hemolymph), and a series of conduits (blood vessels) that transports materials around the body.

- In **open circulatory systems**, extracellular fluid called **hemolymph** leaves vessels and percolates through tissues before returning to the heart. In **closed circulatory systems**, blood—a portion of the extracellular fluid—is contained in a system of vessels. Closed circulatory systems have the ability to selectively direct blood, and therefore hormones and nutrients, to specific tissues. **Review Figure 49.1**

open circulatory system Circulatory system in which extracellular fluid leaves the vessels of the circulatory system, percolates between cells and through tissues, and then flows back into the circulatory system to be pumped out again. (Contrast with closed circulatory system.)

hemolymph The extracellular fluid in closed circulatory systems.

closed circulatory system Circulatory system in which the circulating fluid is contained within a continuous system of vessels. (Contrast with open circulatory system.)

► 49.2 Vertebrate Circulatory Systems Evolved from Single to Double Circuits

- The circulatory system of vertebrates consists of a heart and a closed system of vessels containing blood that is separate from the interstitial fluid. **Arteries** and **arterioles** carry blood from the heart; **capillaries** are the site of exchange between blood and interstitial fluid; **venules** and **veins** carry blood back to the heart.

artery A muscular blood vessel carrying oxygenated blood away from the heart to other parts of the body. (Contrast with vein.)

arteriole A small blood vessel arising from an artery that feeds blood into a capillary bed.

capillaries [L. *capillaris*: hair] Very small tubes, especially the smallest blood-carrying vessels of animals between the termination of the arteries and the beginnings of the veins. **Capillary beds** are networks of capillaries where materials are exchanged between the blood and the interstitial fluid.

venule A small blood vessel draining a capillary bed that joins others of its kind to form a vein. (Contrast with arteriole.)

vein [L. *vena*: channel] A blood vessel that returns blood to the heart. (Contrast with artery.)

- The vertebrate circulatory system evolved from a single circuit in fishes to partially or completely separate pulmonary and systemic circuits in amphibians, reptiles, and mammals.
- In the single-circuit system of fishes, blood flow is unidirectional and is propelled by one-way valves between the [sinus venosus](#) and the [atrium](#), between the atrium and the [ventricle](#), and between the ventricle and the [bulbus arteriosus](#).

sinus venosus The first chamber of the heart of fish that opens into the atrium.

atrium (a' tree um) [L. *atrium*: central hall] An internal chamber. In the hearts of vertebrates, the thin-walled chamber(s) entered by blood on its way to the ventricle(s). Also, the outer ear.

ventricle A muscular heart chamber that pumps blood through the lungs or through the body.

bulbus arteriosus The last chamber of the fish heart.

- In birds and mammals, blood circulates through two completely separate circuits. The [pulmonary circuit](#) transports blood between the heart and lungs, and the [systemic circuit](#) transports oxygen-rich blood between the heart and tissues. **See [Activity 49.1](#)**

pulmonary circuit The portion of the circulatory system by which blood is pumped from the heart to the lungs or gills for oxygenation and back to the heart for distribution. (Contrast with systemic circuit.)

systemic circuit Portion of the circulatory system by which oxygenated blood from the lungs or gills is distributed throughout the rest of the body and returned to the heart. (Contrast with pulmonary circuit.)

▶ 49.3 Heart Function Depends on Properties of Cardiac Muscle

- The mammalian heart has four chambers. Valves in the heart prevent the backflow of blood. **Review [Figure 49.2](#), [Activity 49.2](#)**
- The [cardiac cycle](#) has two phases: [systole](#) refers to the contraction phase, and [diastole](#) refers to the relaxation phase. The sequential heart sounds ("lub-dup") are made by the closing of the heart valves. **Review Focus: Key [Figure 49.4](#), [Animation 49.1](#)**

cardiac cycle Contraction of the two atria of the heart, followed by contraction of the two ventricles and then relaxation.

systole (sis' tuh lee) [Gk. contraction] Contraction of a chamber of the heart, driving blood forward in the circulatory system. (Contrast with diastole.)

diastole (dye ass' toll ee) [Gk. dilation] The portion of the cardiac cycle when the heart muscle relaxes. (Contrast with systole.)

- Blood pressure can be measured using a sphygmomanometer and a stethoscope. **Review [Figure 49.5](#)**
- [Pacemaker cells](#) of the sinoatrial node set the heart rate as a result of the properties of their ion channels. The autonomic nervous system controls heart rate: sympathetic activity increases heart rate, and parasympathetic activity decreases it by altering the rate of depolarization of the pacemaker cell resting membrane potentials following the termination of systole. **Review [Figures 49.6](#), [49.7](#)**

pacemaker cells Cardiac cells that can initiate action potentials without stimulation from the nervous system, allowing the heart to initiate its own contractions.

- The **sinoatrial node** controls the cardiac cycle by initiating a wave of depolarization in the atria, which is conducted to the ventricles through a system consisting of the **atrioventricular node, bundle of His**, and **Purkinje fibers**. **Review Figure 49.8**

sinoatrial node (sigh' no ay' tree al) [L. *sinus*: curve + *atrium*: chamber] The pacemaker of the mammalian heart.

atrioventricular node A modified node of cardiac muscle that organizes the action potentials that control contraction of the ventricles.

Purkinje fibers (pur kin' jee) Specialized heart muscle cells that conduct excitation throughout the ventricular muscle.

- Sustained contraction of ventricular muscle cells is due to long-duration action potentials that are generated by voltage-gated Na^+ and Ca^{2+} channels. **Review Figure 49.9**
- An **electrocardiogram (ECG or EKG)** records electrical events caused by the depolarizations and repolarizations of the cardiac muscles. **Review Figure 49.10**

electrocardiogram (ECG or EKG) A graphic recording of electrical potentials from the heart.

▶ 49.4 Circulatory System Functions Depend on Blood and Blood vessels

- Blood consists of a **plasma** portion (water, salts, and proteins) and a cellular portion (**erythrocytes** or red blood cells, platelets, and white blood cells). All of the cellular components are produced from stem cells in the bone marrow. **Review Figure 49.11**

erythrocyte (ur rith' row site) [Gk. *erythros*: red + *kytos*: container] A red blood cell.

- Erythrocytes transport oxygen. Their production in the bone marrow is stimulated by **erythropoietin**, which is produced in response to **hypoxia** (low oxygen levels) in the tissues.

erythropoietin (EPO) (ur rith' row poi' i tn) A hormone produced by the kidney in response to lack of oxygen that stimulates the production of red blood cells.

hypoxia A deficiency of oxygen.

- **Platelets**, along with circulating proteins, are involved in **blood clotting**, which results in a meshwork of fibrin threads that help seal damaged vessels. **Review Figure 49.12**

platelet A membrane-bounded body without a nucleus, arising as a fragment of a cell in the bone marrow of mammals. Important to blood-clotting action.

blood clotting A cascade of events involving platelets and circulating proteins (clotting factors) that seals damaged blood vessels.

- Abundant smooth muscle cells allow vessels to change their diameter, altering their

resistance and thus blood flow. Arteries have elastic fibers that enable them to withstand high pressures. **Review Figure 49.13, Activity 49.3**

- Capillary beds are the site of exchange of materials between blood and tissue fluid.
- **Starling's forces** suggest that blood volume is maintained in the capillary beds by an exchange of fluids driven by both blood hydrostatic pressure and osmotic pressure. **Review Figure 49.15**

Starling's forces The two opposing forces responsible for water movement across capillary walls: blood pressure, which squeezes water and small solutes out of the capillaries, and osmotic pressure, which pulls water back into the capillaries.

- Bicarbonate ions in the blood plasma contribute to the osmotic forces that draw water back into capillaries.
- The ability of a specific molecule to cross a capillary wall depends on the architecture of the capillary and the chemical characteristics of the molecule.
- Veins have a high capacity for storing blood. Aided by gravity, by contractions of skeletal muscle, and by the actions of breathing, they return blood to the heart. **Review Figure 49.16**
- The **Frank-Starling law** describes forces that increase cardiac output, such as stretch of the cardiac muscles cells caused by increased venous return.
- The **lymphatic system** returns the interstitial fluid to the blood.

► 49.5 The Circulation Is Controlled by Hormonal and Neural Signals

- Blood flow through capillary beds is controlled by local **autoregulatory mechanisms**, hormones, and the autonomic nervous system. **Review Figure 49.18, Activity 49.4**
- Blood pressure is controlled in part by the hormones **ADH** and **angiotensin**, which stimulate contraction of blood vessels. **Review Figure 49.19**

ADH See vasopressin.

angiotensin (an' jee oh ten' sin) A peptide hormone that raises blood pressure by causing peripheral vessels to constrict. Also maintains glomerular filtration by constricting efferent vessels and stimulates thirst and the release of aldosterone.

- Heart rate is controlled by the autonomic nervous system, which responds to information about blood pressure and blood composition that is integrated by regulatory centers in the medulla. **Review Figure 49.20**

Review

9.2 Ectothermic reptiles have the ability to control blood flow to the pulmonary circuit, enabling them to conserve energy when they are not breathing.

Original Paper: Eme, J., J. Gwalthney, T. Owerkowicz, J. M. Blank and J. W. Hicks. 2010. Turning crocodilian hearts into bird hearts: Growth rates are similar for alligators with and without right-to-left cardiac shunt. *Journal of Experimental Biology* 213: 2673-2680.

Crocodilian hearts are four-chambered, just like those of birds and mammals. But crocodiles have two aortas—one from each ventricle—and the flow into each is controlled by a valve. The two aortas are connected by a shunt after they leave the heart. Thus, the right ventricle of the crocodile heart can pump blood to the lungs or to the rest of the body. If the crocodile is breathing, the resistance in the pulmonary circuit is low, and blood flows through the pulmonary artery because high backpressure from the left ventricle exerted through the shunt keeps the right aortic valve shut. When the animal is not breathing, the pulmonary resistance increases, and blood from the right ventricle flows into the right aorta. Researchers tried to demonstrate an adaptive advantage to the aortic shunt in crocodiles.

Working with young American alligators (5-7 months of age), the researchers surgically closed the right aorta near the right ventricle so that blood from the right ventricle could not flow through it to the body but had to flow through the lungs, as in an avian or mammalian circulatory system. The researchers performed sham operations on a similar group of animals, as controls. Sham operations were carried out exactly as the experimental operations, except that the aortas were not actually closed. After the crocodiles recovered from surgery, the researchers divided them into two experimental groups and two control groups that would be either sedentary (no exercise) or that would run on a treadmill to exhaustion three times a week. Over the next 21 months, the researchers measured each animal's body mass and body length every 2 weeks. Animals were provided enough food to satisfy their hunger at each feeding.

Data for each group were subjected to least squares analysis. Bars represent mean values determined for each group, and error bars are the standard errors of the means. The probabilities that the means in each comparison are due to chance alone are shown above the graphs.

Questions

1. Create a diagram like that on p. 1048 showing the path of blood through a crocodilian heart. Mark the diagram to show the surgery done by the research group. On the diagram, show how the surgery changed the blood flow through the crocodilian heart. Write an explanation to accompany your figure. Then explain why the surgery made the crocodilian heart similar to a bird heart.
2. For an alligator, what advantage is gained by being able to shunt blood away from the lungs?
3. What do the data regarding body mass and body length suggest about the effects of blocking blood flowing from the right ventricle to the body? Does this provide evidence in support of the adaptive advantage of having a pulmonary bypass shunt? Explain your answer.
1. The animals in this study were maintained in captivity and supplied with food. How might these conditions limit the potential of the experiment to show an adaptive advantage of the aortic shunt?

► Go to **LaunchPad** for the eBook, LearningCurve, animations, activities, flashcards, and additional resources and assignments. ◀

***connect the concepts** [Key Concept 48.5](#) discusses the mechanisms for sensing CO₂ and O₂ concentrations in the blood. The medullary chemoreceptors are activated by increases in CO₂ levels and decreases in pH, and the carotid and aortic bodies are activated by falling O₂ levels. Chemore-ceptors send signals to the cardiovascular regulatory center as well as to the respiratory regulatory center.

Nutrition, Digestion, and Absorption

In Pima populations, historic occurrences of food deprivation may have imposed selection for genes that improve the efficiency of managing the energy obtained from food. With modern diets and lifestyles, these “thrifty genes” can contribute to obesity and diabetes.

key concepts

[0.1 Food Provides Energy As Well As Materials for Biosynthesis](#)

[0.2 Diverse Adaptations Support Ingestion and Digestion of Food](#)

investigatinglife

Thrifty Phenotypes

For thousands of years the Pima of southwestern North America were hunters and gatherers, supplementing their diet with subsistence agriculture. Their environment was arid, so they developed sophisticated irrigation systems; even so, they frequently encountered drought and subsequent starvation. Today most individuals of the ethnic Pima population in North America are clinically obese. As a population they are one of the heaviest in the world.

Obesity contributes to health problems such as diabetes, high blood pressure, and heart disease. Diabetes incidence in the Pima is seven times the national average. Two-thirds of Pima adults over the age of 40 are diabetic, and diabetes is occurring in younger individuals than previously seen. What has caused such a radical health change in the population? Two interacting factors are involved: genetics and lifestyle.

Geneticists hypothesize that recurring episodes of starvation produce strong selective pressure for “thrifty genes”—particular alleles of the genes involved in digestion, absorption, and energy storage that result in greater-than-average efficiency in converting food into fat. Thrifty genes would carry a strong selective advantage when food is scarce. The Pima display a “thrifty” phenotype. They have low resting metabolic rates and convert food into fat readily. Insulin facilitates conversion of dietary sugar into fat. For many Pima, consuming a standard amount of glucose causes their insulin levels to rise three times higher than it does in people of European ancestry.

Modern lifestyle also plays a role in the Pima obesity epidemic. Instead of eating their traditional diet, the Pima now eat a high-calorie, high-fat Western diet, and they engage in less physical activity than their ancestors did. A population of Pima living in the Sierra Madre of northern Mexico are genetically the same as the Arizona population. However, they eat traditional foods and live a traditional lifestyle that involves much physical activity. Obesity and diabetes are not prevalent among the Mexico Pima.

A high-calorie diet and sedentary lifestyle affect not just the Pima but contribute to the overall increase in obesity throughout the U.S. population. Recently an additional factor that might contribute to obesity and diabetes has been discovered—the type of food that is eaten. The composition of the diet influences the populations of gut microbes, and those microbes influence outcomes of digestion. Apparently calories are not all equal; their impact depends on their origin.

QA If the nutritional values were the same, could different foods have different impacts on health?

50.1 Food Provides Energy As Well As Materials for Biosynthesis

Animals are **heterotrophs**—they derive their nutrition from eating other organisms. In contrast, **autotrophs** (most plants, some bacteria, some archaea, and some protists) can use solar energy or inorganic chemical energy to synthesize all of their components. Of course, some **plants** are also heterotrophs.

heterotroph (het' er oh trof) [Gk. *heteros*: different + *trophe*: feed] An organism that requires preformed organic molecules as food. (Contrast with autotroph.)

autotroph (au' tow trowf) [Gk. *autos*: self + *trophe*: food] An organism that is capable of living exclusively on inorganic materials, water, and some energy source such as sunlight (photoautotrophs) or chemically reduced matter (see chemoautotrophs). (Contrast with heterotroph.)

focus your learning

Fats, carbohydrates, and proteins in food provide energy.

Energy is stored in animal bodies as glycogen and fat.

Some small organic molecules required for biosynthesis, including essential amino acids and fatty acids, must come from food.

Vitamins are organic compounds that the animal cannot synthesize but are required for healthy cell function.

Animals require a variety of mineral nutrients.

Directly and indirectly, heterotrophs take advantage of—indeed, depend on—the organic synthesis carried out by autotrophs and have evolved an enormous diversity of adaptations to exploit this resource (**Figure 50.1**). In this section we describe how animals use food, be it plants or other animals, to obtain energy and building blocks of complex molecules. We also consider the need for special mineral nutrients and organic molecules and the diseases that result when they are lacking in the diet.

(A)

(B)

Figure 50.1 Heterotrophs Get Energy from Autotrophs (A) Herbivores get their energy directly from autotrophs. The large herbivores of the African grasslands must consume huge amounts of plant matter to fulfill their nutritional needs. **(B)** A carnivore's energy is indirectly obtained from autotrophs, since the energy stored in a prey animal was originally obtained from autotrophs.

Energy needs and expenditures can be measured

Energy—the capacity to do work—comes in different forms, including electric, heat, chemical, and nuclear energy. As discussed in [Chapter 8](#), a calorie (note the small c) is a unit of heat energy; specifically, it is the amount of heat necessary to raise the temperature of 1 gram of water 1°C. Because this is such a tiny amount of energy, physiologists commonly use the [kilocalorie \(kcal\)](#) as a unit of measure (1 kcal = 1,000 calories). Nutritionists also use the kilocalorie as a standard unit of energy, but they traditionally refer to it as the [Calorie \(Cal\)](#), which is capitalized to distinguish it from the single calorie.

kilocalorie (kcal) See calorie.

calorie [L. *calor*: heat] The amount of heat required to raise the temperature of 1 gram of water by 1°C. Physiologists commonly use the kilocalorie (kcal) as a unit of measure (1 kcal = 1,000 calories). Nutritionists also use the **kilocalorie**, but refer to it as the **Calorie (Cal, capital C)**.

Just about any food container you pick up in the United States carries the label “Nutrition Facts,” which includes the item “Calories.” How do Calories (or kcal) relate to the discussion in [Chapter 9](#) about how energy in the chemical bonds of food molecules is transferred to the high-energy phosphate bonds of adenosine triphosphate (ATP) and is then used to do cellular work? And why do we use heat energy as a measure of nutrition?

The reason is found in the ***laws of thermodynamics**, which tell us that energy cannot be created or destroyed, but can be converted from one form to another.

However, every energy conversion is inefficient; a large portion of the original energy always ends up as heat. Whether we are using the energy in glucose to make ATP or are using that ATP to power muscle contraction or ion transport, most of the available chemical energy is lost as heat. The bottom line is that if an animal is not growing, not doing any external work, and not changing its body temperature, the heat it loses to the environment is a measure of its total energy expenditure, or metabolism.

An animal's energy needs must be met by the ingestion, digestion, and assimilation of food. The basal energy expenditure (basal metabolic rate, BMR) of a human is 1,300-1,500 Cal/day for an adult female and 1,600-1,800 Cal/day for an adult male. Any physical activity adds to the BMR. For a person doing sedentary work, about 30 percent of the total Calories expended are used for skeletal muscle activity; for a person doing heavy physical labor, more than 95 percent of caloric expenditure is for skeletal muscle activity.

The components of food that provide energy are fats, carbohydrates, and proteins. Fats yield 9.5 Cal/gram, carbohydrates 4.2 Cal/gram, and proteins about 4.1 Cal/gram. [Figure 50.2](#) shows some equivalencies of food, energy, and energy consumption.

Figure 50.2 Food Energy and How We Use It The energy contained in four common food items is shown at the left. The graphs indicate about how long it would take a person with a basal energy requirement of about 1,800 Cal/day to use the equivalent amount of energy while resting, walking, or jogging.

Even though the units calorie, kilocalorie, and Calorie remain in popular use, most scientists now use the International System of Units (ISU). In this system the basic unit of energy is the joule: 1 joule = 0.239 calories, and the measure of energy use is 1 joule/second = 1 watt. You

are familiar with light bulb ratings, so think about that when you convert kcal/day into watts. The 1,700 Cal/day energy expenditure of the average man converts to 82 watts (note that a watt includes the time dimension, so it is a rate of energy use).

Thus it is possible to quantify the caloric value of any food an animal eats. It is also possible to quantify the caloric expenditure of any activity or behavior an animal performs. By comparing calories consumed with calories expended, we can construct [energy budgets](#) that allow ecologists and evolutionary biologists to apply a [*cost-benefit analysis](#) to feeding behavior.

energy budget A quantitative description of all paths of energy exchange between an animal and its environment.

Sources of energy are stored in the body

Although cells of the body use energy continuously, most animals do not eat continuously and so must store fuel molecules that can be released as needed between meals. Carbohydrates are stored in the liver and in muscle cells as glycogen, but the total glycogen stored represents only about a day's basal energy requirement. Fat is the most important form of stored energy in the bodies of animals. Not only does fat have more energy per gram than glycogen, but it can be stored with little associated water, making it more compact and less expensive to carry. Migrating birds store energy as fat to fuel their long flights; if they had to store the same amount of energy as glycogen, they would be too heavy to fly. Proteins are not used as energy storage compounds, but the body's proteins can be metabolized as an energy source of last resort.

If an animal takes in too little food to meet its energy requirements, it starts to metabolize some of the molecules of its own body. This "self-consumption" begins with the energy storage compounds glycogen and fat. Once fat reserves are seriously depleted, the body increases its metabolism of proteins for energy ([Figure 50.3A](#)). The first proteins to be sacrificed are those of the blood plasma. The loss of plasma proteins decreases the osmotic concentration of the plasma, resulting in increased loss of fluid from the blood to the interstitial spaces (edema). Accumulation of fluid in the extremities and abdomen is the classic sign of kwashiorkor, a disease caused by chronic protein deficiency ([Figure 50.3B](#)). Continued protein loss damages the body's organs, eventually leading to death.

Figure 50.3 The Course of Starvation **(A)** When a person is subjected to undernutrition, the body's energy reserves are depleted. **(B)** The swollen abdomen, hands, and feet of this boy are due to edema. Along with his spindly limbs, these are symptoms of kwashiorkor, a disease resulting from the body breaking down blood proteins and muscle tissue to fuel metabolism.

When an animal consistently takes in more food than it needs to meet its energy requirements, the excess nutrients are stored as increased body mass. First glycogen reserves build up; then additional dietary carbohydrates, fats, and proteins are converted to body fat. In some species, such as hibernators, seasonal overnutrition is an important adaptation for surviving periods when food is not available. In humans, however, overnutrition can be a serious health hazard, increasing the risk of high blood pressure, heart attack, diabetes, and other disorders, as seen in the Pima that were discussed in the chapter opener.

Food provides carbon skeletons for biosynthesis

Every animal must take in certain organic molecules that it cannot synthesize for itself but needs to form the building blocks of its own complex organic molecules. The acetyl group ($\text{CH}_3\text{CO}-$) is one such required building block, supplying the **carbon skeleton** of larger organic molecules (**Figure 50.4**). Animals cannot synthesize acetyl groups from carbon, oxygen, and hydrogen molecules but must obtain them from food. Acetyl groups can be derived from the metabolism of almost any food, but they originate in plants.

carbon skeleton The chains or rings of carbon atoms that form the structural basis of organic molecules. Other atoms or functional groups are attached to the carbon atoms.

Figure 50.4 The Acetyl Group Is an Acquired Carbon Skeleton Animals cannot synthesize the acetyl group for themselves, but they ingest it in their food and use it to synthesize a wide variety of molecules.

Acetyl groups are never in short supply for an adequately nourished animal. However, some groups supplying carbon skeletons can be deficient in an animal's diet even if caloric intake is adequate. One such group includes certain amino acids, the building blocks of proteins. Animals can synthesize some of their own amino acids using carbon skeletons from acetyl or other groups and transferring to them amine groups ($-\text{NH}_2$) derived from other amino acids. However, most animals cannot synthesize all the amino acids they need and thus must obtain certain **essential amino acids** from food. If an animal does not take in enough of even one of its essential amino acids, its protein synthesis is impaired and its capacity to maintain enzymatic and transport functions is challenged.

essential amino acids Amino acids that an animal cannot synthesize for itself and must obtain from its food.

Essential amino acids vary by species. Most researchers agree that adult humans must obtain eight essential amino acids from their food: isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, and valine. All eight are available in milk, eggs, meat, and soybean products, but most plant foods do not contain adequate quantities of all eight, so a strict vegetarian diet carries a risk of protein malnutrition. **A complementary diet** of plant foods, however, supplies all eight essential amino acids (**Figure 50.5**). In general, grains (such as rice, wheat, and corn) are complemented by legumes (such as beans and peas). Long before the chemical basis for complementarity was understood, societies with little access to meat developed complementary diets. Many Central and South American peoples traditionally eat beans with corn, and the native peoples of North America complemented their beans with squash.

Figure 50.5 A Strategy for Vegetarians By combining cereal grains with legumes, an adult vegetarian can obtain all eight essential amino acids.

Human infants are thought to require four additional amino acids in their diets: histidine, tyrosine, cysteine, and arginine. Also, some amino acids are required by individuals with certain metabolic disorders who cannot synthesize them adequately. For example, individuals with the genetic disease phenylketonuria lack the enzyme for converting phenylalanine to tyrosine (see [Key Concept 15.2](#)) and must obtain tyrosine from their diets. They must keep their dietary intake of phenylalanine low to prevent its accumulation to toxic levels.

Why are dietary proteins completely digested to their constituent amino acids before being used by the body? Wouldn't it be more energy-efficient to reuse some dietary proteins directly? There are several reasons why ingested proteins are not used "as is":

Macromolecules such as proteins are not readily absorbed by the cells of the gut, but their constituent monomers (such as amino acids) are readily absorbed.

Protein structure and function are highly species-specific. A protein that functions optimally in one species might not function well in another.

Foreign proteins entering the body directly from the gut would be recognized as invaders and would be attacked by the immune system.

Humans can synthesize almost all the lipids required by the body using acetyl groups obtained from food (see [Figure 50.4](#)), but we must have a dietary source of two **essential fatty acids**—linoleic acid and alpha-linolenic acid—that we cannot synthesize. Linoleic acid is needed by mammals to synthesize other unsaturated fatty acids, such as arachidonic acid, which is a component of several signaling molecules, including prostaglandins. Essential fatty acids are also necessary components of membrane phospholipids. A deficiency of linoleic acid can lead to problems such as infertility and impaired lactation, but because it is commonly present in vegetable oils, a deficiency is unlikely in an adequately nourished individual.

essential fatty acids Fatty acids that an animal cannot synthesize for itself and must obtain from its food.

Animals need mineral elements for a variety of functions

Principal mineral elements that animals require are listed in [Table 50.1](#). Elements required in

large amounts are called [macronutrients](#); those required in only tiny amounts (generally less than 100 mg/day) are called [micronutrients](#). Some micronutrients are required in such minute amounts that deficiencies are never observed, but they are nevertheless essential elements.

macronutrient In plants, a mineral element required in concentrations of at least 1 milligram per gram of plant dry matter; in animals, a mineral element required in large amounts. (Contrast with micronutrient.)

micronutrient In plants, a mineral element required in concentrations of less than 100 micrograms per gram of plant dry matter; in animals, a mineral element required in concentrations of less than 100 micrograms per day. (Contrast with macronutrient.)

table 50.1 Mineral Elements Required by Animals

Element	Source in human diet	Major functions
MACRONUTRIENTS		
Calcium (Ca)	Dairy foods, eggs, green leafy vegetables, whole grains, legumes, nuts, meat	Found in bones and teeth; blood clotting; nerve and muscle action; enzyme activation
Chlorine (Cl)	Table salt (NaCl), meat, eggs, vegetables, dairy foods	Water balance; digestion (as HCl); principal negative ion in extracellular fluid
Magnesium (Mg)	Green vegetables, meat, whole grains, nuts, milk, legumes	Required by many enzymes; found in bones and teeth
Phosphorus (P)	Dairy, eggs, meat, whole grains, legumes, nuts	Component of nucleic acids, ATP, and phospholipids; bone formation; buffers; metabolism of sugars
Potassium (K)	Meat, whole grains, fruits, vegetables	Nerve and muscle action; protein synthesis; principal positive ion in cells
Sodium (Na)	Table salt, dairy foods, meat, eggs	Nerve and muscle action; water balance; principal positive ion in extracellular fluid
Sulfur (S)	Meat, eggs, dairy foods, nuts, legumes	Found in proteins and coenzymes; detoxification of harmful substances
MICRONUTRIENTS		
Chromium (Cr)	Meat, dairy, whole grains, legumes, yeast	Glucose metabolism
Cobalt (Co)	Meat, tap water	Found in vitamin B ₁₂ ; formation of red blood cells
Copper (Cu)	Liver, meat, fish, shellfish, legumes, whole grains, nuts	Found in active site of many redox enzymes and electron carriers; production of hemoglobin; bone formation
Fluorine (F)	Most municipal water supplies	Found in teeth; helps prevent tooth decay
Iodine (I)	Fish, shellfish, iodized salt	Found in thyroid hormones
Iron (Fe)	Liver, meat, green vegetables, eggs, whole grains, legumes, nuts	Found in active sites of many redox enzymes and electron carriers, hemoglobin, and myoglobin
Manganese (Mn)	Organ meats, whole grains, legumes, nuts, tea, coffee	Activates many enzymes
Molybdenum (Mo)	Organ meats, dairy, whole grains, green vegetables, legumes	Found in some enzymes
Selenium (Se)	Meat, seafood, whole grains, eggs, milk, garlic	Fat metabolism

Zinc (Zn)

Liver, fish, shellfish, and many other foods

Found in some enzymes and some transcription factors; insulin physiology

Calcium is an example of a macronutrient. It is the fifth most abundant element in the body; a 70-kg person contains about 1.2 kg of calcium. Calcium phosphate is the principal structural material in bones and teeth. Muscle contraction, neural function, and many other intracellular functions in animals require ***calcium ions (Ca^{2+})**. The turnover of calcium in the extracellular fluid is high, as bones are constantly being remodeled and calcium is constantly entering and leaving cells. Calcium is lost from the body in urine, sweat, and feces, so it must be replaced regularly. Adult humans require 800-1,000 mg of calcium per day in their diet.

Iron is an example of a micronutrient. It is found throughout the body because it is the oxygen-binding atom in hemoglobin and myoglobin and is a component of enzymes in the respiratory chain. Nevertheless, the total amount of iron in a 70-kg person is only about 4 g, and since iron is recycled efficiently in the body and is not lost in the urine, we require only about 15 mg per day in our food. Despite the small amount required, insufficient iron is the most common mineral nutrient deficiency in the world today. Iron deficiency leads to anemia, a condition that renders individuals weak and tired all the time.

Activity 50.1 Mineral Elements Required by Animals www.Life11e.com/ac50.1

Animals must obtain vitamins from food

Like essential amino acids and fatty acids, vitamins are carbon compounds that an animal requires for growth and metabolism but cannot synthesize for itself. Most vitamins function as coenzymes or parts of coenzymes (see [Key Concept 8.4](#)).

Each species has its own vitamin requirements. Primates, for example, require vitamin C (ascorbic acid). While most mammals can make their own ascorbic acid, primates (including humans) cannot, so for primates, ascorbic acid is a vitamin. If we do not get vitamin C in our food, we develop scurvy, a disease characterized by bleeding gums, loss of teeth, subcutaneous hemorrhages, and slow wound healing. Scurvy was a frequently fatal problem for sailors on long voyages until late in the eighteenth century, when a Scottish physician, James Lind, discovered that the disease could be prevented if the sailors ate fresh greens and citrus fruit. The British Admiralty made limes standard provisions for its ships (and British sailors have been called “limeys” ever since). When the active ingredient in limes was isolated, it was named ascorbic (“without scurvy”) acid.

Humans require 13 vitamins; these are divided into two groups, water-soluble and fat-soluble ([Table 50.2](#)). When water-soluble vitamins are ingested in excess of bodily needs, they are simply eliminated in the urine. (This is the fate of much of the large doses of vitamin C that people take.) Fat-soluble vitamins, however, can accumulate in body fat and may build up to toxic levels in the liver if taken in excess.

table 50.2 Vitamins in the human Diet

Vitamin	Source	Function	Deficiency symptoms
WATER-SOLUBLE			
B ₁ (thiamin)	Liver, legumes, whole grains	Coenzyme in cellular	Beriberi, loss of appetite, fatigue
B ₂ (riboflavin)	Dairy, meat, eggs, green leafy vegetables	Coenzyme in FAD	Lesions in corners of mouth, eye irritation, skin disorders
B ₃ (niacin)	Meat, fowl, liver, yeast	Coenzyme in NAD and NADP	Pellagra, skin disorders, diarrhea, mental

B ₅ (pantothenic acid)	Liver, eggs, yeast	Found in acetyl CoA	Adrenal problems, reproductive problems
B ₆ (pyridoxine)	Liver, whole grains, dairy foods	Coenzyme in amino acid metabolism	Anemia, slow growth, skin problems, convulsions
B ₇ (biotin)	Liver, yeast, bacteria in gut	Found in coenzymes	Skin problems, loss of hair
B ₁₂ (cobalamin)	Liver, meat, dairy foods, eggs	Formation of nucleic acids, proteins, red blood cells	Pernicious anemia
Folic acid	Vegetables, eggs, liver, whole grains	Coenzyme in formation of heme and nucleotides	Anemia
C (ascorbic acid)	Citrus fruits, tomatoes, potatoes	Formation of connective tissues; antioxidant	Scurvy, slow healing, poor bone growth

FAT-SOLUBLE

A (retinol)	Fruits, vegetables, liver, dairy	Found in visual pigments	Night blindness
D (calciferol)	Fortified milk, fish oils, sunshine	Absorption of calcium and phosphate	Rickets
E (tocopherol)	Meat, dairy foods, whole grains	Muscle maintenance, antioxidant	Anemia
K (menadione)	Intestinal bacteria, liver	Blood clotting	Blood clotting problems

The fat-soluble vitamin D (calciferol), which is essential for absorbing and metabolizing calcium, is a special case because the body can synthesize it. (As noted in [Key Concept 40.4](#), vitamin D is by definition a hormone.) Certain lipids present in the human body can be converted into vitamin D by the action of ultraviolet light on the skin. Thus vitamin D must be obtained in the diet by individuals with inadequate exposure to the sun.

The need for vitamin D may have been an important factor in the evolution of skin color. For humans living in equatorial and low latitudes, dark skin pigmentation is adaptive, as it is a protection against the damaging effects of ultraviolet radiation. These peoples generally expose extensive areas of skin to the sun on a regular basis, so their skin synthesizes adequate amounts of vitamin D. Most races that adapted to life in the higher latitudes lost this dark skin pigmentation, probably because lighter skin facilitates vitamin D production in the relatively small areas of skin exposed to sunlight during the short days of winter. The dark-skinned Inuit peoples of the Arctic are an exception to the correlation between latitude and skin pigmentation, but the Inuit obtain ample vitamin D from the large amounts of animal fat (especially whale blubber) and fish oils in their diet.

Activity 50.2 **Vitamins in the Human Diet** www.Life11e.com/ac50.2

Nutrient deficiencies result in diseases

The lack of an essential nutrient in the diet produces a state of [malnutrition](#), and chronic malnutrition leads to a characteristic [deficiency disease](#) (see [Table 50.2](#)). We discussed kwashiorkor (protein deficiency) and scurvy (vitamin C deficiency). Another deficiency disease, beriberi, was directly involved in the discovery of vitamins.

malnutrition A condition caused by lack of any essential nutrient.

deficiency disease A condition (e.g., scurvy and beriberi) caused by chronic lack of any essential nutrient.

Beriberi, which means “extreme weakness,” became prevalent in Asia in the nineteenth century when it became standard practice to mill rice to a white polish and discard the hulls present in brown rice. A critical observation was that chickens and pigeons developed beriberi-like symptoms when they were fed only polished rice. In 1912 Casimir Funk, a Polish scientist working in England, cured pigeons of beriberi by feeding them discarded rice hulls.

At the time of Funk’s discovery, all diseases were thought either to be caused by microorganisms or to be inherited. Funk suggested that beriberi and some other diseases are dietary in origin and result from deficiencies in specific substances. Funk coined the term “vitamines” from “vital amines” because he mistakenly thought that all these substances vital for life were compounds with amine groups. In 1926 thiamin (vitamin B₁)—the substance lost in the rice milling process—was the first vitamin to be isolated in pure form.

Deficiency diseases can also result from an inability to absorb or process an essential nutrient even if it is present in the diet. Vitamin B₁₂ (cobalamin), for example, is present in all foods of animal origin. Since plants neither use nor produce vitamin B₁₂, a strictly vegetarian diet (not supplemented with dairy products or vitamin pills) can lead to a B₁₂ deficiency disease called pernicious anemia, characterized by a failure of red blood cells to mature. The most common cause of pernicious anemia, however, is not a lack of vitamin B₁₂ in the diet but an inability to absorb it. Normally cells in the stomach lining secrete a peptide called intrinsic factor that binds to vitamin B₁₂ and makes it absorbable by the small intestine. Conditions that damage the stomach lining, such as alcoholism or gastritis, can thus lead to pernicious anemia.

Inadequate mineral nutrition can also lead to deficiency diseases. Examples are hypothyroidism and goiter resulting from iodine deficiency (see [Key Concept 40.4](#)), and anemia resulting from iron deficiency. Iodine deficiency is almost unheard of in the developed world because we add iodide to salt. However, it is still a major health problem in large segments of the human population.

50.1 recap

As heterotrophs, animals must obtain the energy and molecular building blocks for biosynthesis from their food. Energy can come from the metabolism of carbohydrates, fats, and proteins. Molecular building blocks include carbon skeletons, vitamins, and minerals. Lack of essential nutrients results in deficiency diseases.

learning outcomes

You should be able to:

- Describe energy storage adaptations in animal species.
- Discuss challenges related to obtaining all essential amino acids from the diet.
- Discuss examples of mineral macro- and micronutrients and their functions.
- Compare water-soluble and fat-soluble vitamins and their effects on an animal's body.

1. Gray whales migrate each year from their summer range off Alaska to their winter range off Mexico. During their migrations and their stay in Mexican waters, they eat very little, if

anything. What is their energy source over this long time, and what are the advantages of this energy source?

2. Inuit peoples do not eat polar bear liver because it contains so much vitamin A that consuming it produces a serious disease called hypervitaminosis A. Why isn't there a disease called hypervitaminosis C?
3. Anemia is lack of the micronutrient iron. The incidence of anemia is greater in premenopausal women than in men. Why?
4. A comatose patient is fed a nutrient mix through a food tube into the stomach, but a person with a nonfunctional gastrointestinal system will receive a nutrient mix via blood vessels. Mixes introduced into the stomach include proteins, but mixes delivered into blood vessels do not. Explain why this is, and what must take the place of proteins in the mix delivered into blood vessels.

We have surveyed the essential elements of nutrition in animals. Next we will look at various methods and adaptations by which animals obtain the food they need, and the mechanisms they use to extract nutrients from their food.

***connect the concepts** Carnivorous and parasitic plants are discussed in [Key Concept 35.5](#).

***connect the concepts** The laws of thermodynamics and their application to biological energetics are described in [Key Concept 8.1](#).

***connect the concepts** Any behavior involves energetic costs, opportunity costs, and risk costs and can be measured in terms of its effect on reproductive success. [Key Concept 52.4](#) explores costs and benefits of various behaviors, illustrating how measures of metabolism permit quantitative analysis of evolutionary adaptations.

***connect the concepts** Many physiological processes are affected by Ca^{2+} ; therefore it is essential that the blood levels stay between 9 and 11 mg/100 mL. This is only 0.1 percent of the Ca^{2+} in the body. About 1 percent is intracellular and 99 percent is in the bones, thus it is a challenge to maintain tiny, but critical, blood levels in the face of such huge reservoirs. Hormonal regulation of blood calcium is discussed in [Key Concept 40.4](#), and the cellular mechanisms are discussed in [Key Concept 47.1](#).

50.2 Diverse Adaptations Support Ingestion and Digestion of Food

Heterotrophic organisms can be classified by how they acquire their nutrition. **Saprobies** (also called saprotrophs) are organisms that absorb nutrients from dead organic matter. Most saprobies are either protists or fungi. **Detritivores**, or **decomposers**, such as earthworms and crabs, actively feed on dead organic material. Animals that feed on living organisms are **predators**: **herbivores** prey on plants, **carnivores** prey on animals, and **omnivores** prey on both. **Filter feeders**, such as clams and blue whales, prey on small organisms by filtering them from the aquatic environment. **Fluid feeders** include mosquitoes, aphids, leeches, and hummingbirds. The anatomical adaptations that enable a species to exploit a particular source of nutrition are usually obvious, but physiological and biochemical adaptations are also important.

saprobe [Gk. *sapros*: rotten] An organism (usually a bacterium or fungus) that obtains its carbon and energy by absorbing nutrients from dead organic matter. Also called a saprotroph.

detritivore (di try' ti vore) [L. *detritus*: worn away + *vorare*: to devour] An organism that obtains its energy from the dead bodies or waste products (**detritus**) of other organisms, releasing nutrients and energy. (Contrast with carnivore, herbivore, omnivore.)

decomposer See detritivore.

predator An organism that kills and/or consumes individuals (or parts of individuals) of another species (its prey).

herbivore (ur' bi vore) [L. *herba*: plant + *vorare*: to devour] An animal that eats plant tissues. (Contrast with carnivore, detritivore, omnivore.)

carnivore [L. *carn*: flesh + *vorare*: to devour] An organism that eats animal tissues. (Contrast with detritivore, herbivore, omnivore.)

omnivore [L. *omnis*: everything + *vorare*: to devour] An organism that feeds on multiple trophic levels; also an organism that feeds on animals and primary producers. (Contrast with carnivore, detritivore, herbivore.)

filter feeder An organism that feeds on organisms much smaller than itself that are suspended in water or air by means of a straining device. Also called suspension feeder.

fluid feeder An animal that feeds on fluids it extracts from the bodies of other organisms; examples include nectar-feeding birds and bloodsucking insects.

focus your learning

Heterotrophs display a wide diversity of adaptations for acquiring and processing food.

Digestion occurs in a body cavity where secreted enzymes break down large molecules into small molecules that cells can absorb.

Heterotrophs rely on symbiotic bacteria residing in their digestive system to carry out essential tasks in digestion.

The food of herbivores is often low in energy and hard to digest

Most vegetation is coarse, difficult to break down, and has low energy content. Therefore herbivores spend a great deal of time feeding and processing their food. Many have striking adaptations for feeding, such as the trunk (a flexible, gripping nose) of the elephant or the huge bill of the fruit-eating toucan, which can be half as long as its body. Many types of grinding, rasping, cutting, and shredding mouthparts have evolved in invertebrates for ingesting plant material, and the teeth of herbivorous vertebrates have been shaped by selection to tear, crush, and grind coarse plant matter.

The elephant provides an example of the importance of teeth. Elephants have six chewing teeth per quadrant, which appear one at a time. The first is present at birth, and subsequent ones appear at the back of the jaw and move forward as the elephant ages. The first falls out at 2-3 years of age, the second at 4-6 years of age, and so forth until the last, and biggest, one (20 cm long and 4 kg) is worn out sometime past 60 years of age. With the loss of that last tooth, the elephant starves and dies.

The digestive processes of herbivores can be quite specialized. An example is the koala, which almost exclusively eats leaves of eucalyptus trees. These leaves are very fibrous, low in usable energy and protein, and high in toxic chemicals. The koala has strong jaws for grinding the leaves, a very long gut for fermenting them, enzymes in its liver for detoxifying chemicals in the leaves, and a low metabolic rate (i.e., it expends little energy) to compensate for low energy intake.

Carnivores must find, capture, and kill prey

The predatory behaviors of many carnivores are legendary—the hunting skills of hawks, wolves, and tigers, for example. Carnivores have evolved stealth, speed, power, large jaws, sharp teeth, and strong gripping appendages. They also have evolved remarkable means of detecting prey. Bats use echolocation, pit vipers sense infrared radiation from the warm bodies of their prey, and certain fishes detect electric fields created in the water by their prey. There are many fascinating examples of adaptations for capturing prey, such as the immobilizing venom of many snakes, the long sticky tongues of chameleons, and the webs of spiders.

Some predators digest their prey externally. For example, a spider injects insect prey with digestive enzymes and then sucks out the liquefied contents, leaving behind the empty exoskeletons frequently seen in old spider webs. The majority of animals, however, digest their food internally. For many, the process of digestion begins with the physical breaking down of the food items by the teeth.

Vertebrate species have distinctive teeth

Teeth are adapted for the acquisition and initial processing of specific types of foods. Because they are among the hardest structures of the body, an animal's teeth remain in the environment long after it dies. Paleontologists use teeth to identify animals that lived in the distant past and to deduce their feeding behavior.

In general, teeth of all vertebrates have the same, three-layered structure (**Figure 50.6A**). An extremely hard material called **enamel**, composed principally of calcium phosphate, covers the crown of the tooth. Both the crown and root contain a layer of bony material called **dentine**, inside of which is a **pulp cavity** containing blood vessels, nerves, and the cells that produce the dentine.

enamel The hard material, composed primarily of calcium phosphate, that covers the tooth.

dentine The layer of dense bony material beneath the enamel of the tooth.

pulp cavity The space in the interior of the tooth that contains blood vessels, nerves, and dentine-producing cells.

Figure 50.6 Mammalian Teeth (A) A mammalian tooth has three layers: enamel, dentine, and a pulp cavity. **(B)** The teeth of different mammalian species are specialized for different diets. This illustration depicts the teeth of the lower jaw, viewed from above.

 Activity 50.3 Mammalian Teeth www.Life11e.com/ac50.3

There is a great deal of homology in the dentition of mammals, but the shapes and organization of mammalian teeth are adaptations to different diets (**Figure 50.6B**). In general, incisors are used for cutting, chopping, and gnawing; canines are used for stabbing, gripping, and ripping; and molars and premolars (the cheek teeth) are used for shearing, crushing, and grinding. The highly varied diet of humans is reflected in our multipurpose set of teeth, as is common among omnivores.

Digestion usually begins in a body cavity

Animals take food into a body cavity that is continuous with the outside environment. They secrete digestive enzymes into that cavity, and the enzymes break down the food into nutrient molecules that can be absorbed by the cells lining the cavity.

The simplest digestive system is found in the simplest animals such as sponges. Water flows from the environment through the body of the sponge in water channels, and individual cells capture food particles from the water (see **Figure 30.2B**). A slightly more specialized digestive system is a **gastrovascular cavity**, which connects to the outside world through a single opening. Cnidarians, such as jellyfishes, capture prey using stinging nematocysts and use their tentacles to cram the prey into their gastrovascular cavity. Enzymes in the gastrovascular cavity partially digest the prey. Cells lining the cavity take in small food particles by endocytosis. The vesicles created by endocytosis then fuse with lysosomes containing digestive enzymes, and intracellular digestion completes the breakdown of the food. Nutrients are released to the cytoplasm as the vesicles break down.

gastrovascular cavity Serving for both digestion (gastro) and circulation (vascular); in particular, the central cavity of the body of jellyfish and other cnidarians.

Tubular guts have an opening at each end

Animals classified as bilaterians (see [Key Concept 30.1](#)) have a tubular digestive system called a [gastrointestinal system](#) or more simply [gut](#). The gut begins with a mouth that takes in food. The food is moved through the length of the gut as it is sequentially disassembled or digested, and the smallest units of the digested food are absorbed across the gut wall. Solid digestive wastes are eliminated through an [anus](#). Different regions in the tubular gut are specialized for particular functions ([Figure 50.7](#)). These functions must be coordinated so they occur in the proper sequence, and they must be regulated so they occur slowly enough to allow complete digestion but quickly enough to supply the energy needs of the animal.

gastrointestinal system See gut.

gut An animal's digestive tract.

anus (a' nus) An opening through which solid digestive wastes are expelled, located at the posterior end of a tubular gut.

Earthworm

Cockroach

Rabbit

Figure 50.7 Compartments for Digestion and Absorption Most invertebrates and all vertebrates have a tubular gut that begins with a mouth where food is taken in, and ends in an anus where waste is eliminated. Between these two structures are specialized regions for digestion and nutrient absorption; the structures in these regions are adapted to different diets and vary from species to species.

In the mouth cavity, food may be physically fragmented by teeth (in many vertebrates), by a **radula** (in snails), or by **mandibles** (in many arthropods). In most birds, food is ground by small stones in an early, muscular portion of the gut called the **gizzard**. Some animals, such as snakes, simply ingest whole prey with little or no fragmentation. Teeth in these species are angled backward to keep the prey moving in only one direction while being slowly swallowed. **Stomachs and crops** are storage chambers that enable animals to ingest relatively large

amounts of food when it is available, and then digest it gradually. In these storage chambers, food may be further fragmented and mixed, and in most vertebrates it is an important site of digestion. Food delivered into the next section of the gut, the [intestine](#), is in small particles, well mixed, and usually partially digested.

radula A rasplike structure used for scraping food particles off a surface.

mandible A crushing part of arthropod mouth parts, in mammals, the lower jaw bone, in birds the upper or lower part of the beak.

gizzard (giz' erd) [L. *gigeria*: cooked chicken parts] The second of two stomachlike organs in birds, other reptiles, earthworms, and various insects, that grinds up food, sometimes with the aid of fragments of stone. (See also crop.)

intestine The portion of the gut following the stomach, in which most digestion and absorption occurs.

Most digestion occurs in the intestine, and nutrients, water, and ions are absorbed across its walls. Glands secrete digestive enzymes into the intestine, and other enzymes are produced and secreted by cells lining the intestine. The final segment of the intestine recovers water and ions and stores undigested wastes, or feces, so they can be released to the environment at an appropriate time or place. A muscular [rectum](#) near the anus assists in expelling feces.

rectum The terminal portion of the gut, ending at the anus.

In many animals, the parts of the gut that absorb nutrients have greater surface areas than would be expected of a simple tube. The simplest way to increase the surface area of a tube without changing its diameter is to produce an infolding. Such an infolding of the gut, called a typhlosole, is seen in earthworms ([Figure 50.8A](#)). Sharks, which have large stomachs but short intestines, have a unique adaptation called a spiral valve ([Figure 50.8B](#)). The lower region of the intestine is enlarged and has an internal structure that forces the food to pass through it in a spiral fashion (like going down a spiral staircase). The walls of the spiral present a large surface area for absorption of nutrients. This spiral passage, however, will not accommodate large chunks of food or undigestible matter, so food remains in the stomach for a long time to be broken down, and some larger, undigestible items do not leave the stomach except by regurgitation.

Figure 50.8 Intestinal Surface Area and Nutrient Absorption Maximizing the surface area of the gut increases an animal's ability to absorb nutrients.

In humans, as in most other vertebrates, the wall of the intestine is highly folded, with the individual folds bearing legions of tiny fingerlike projections called **villi** (Figure 50.8C). The cells that line the surfaces of the villi, in turn, have microscopic projections called **microvilli**. The microvilli give the intestine an enormous internal surface area for absorbing nutrients.

villi (vil' lus) (singular: villus) [L. *villus*: shaggy hair or beard] Hairlike projections from a membrane; for example, from many gut walls.

microvilli (singular: microvillus) Projections of epithelial cells, such as the cells lining the small intestine, that increase their surface area.

Digestive enzymes break down complex food molecules

Protein, carbohydrate, and fat macromolecules are broken down into their simplest monomeric units by hydrolytic enzymes produced at different locations in the digestive tract. Many are secreted into the lumen of the gut, and others remain associated with the membranes of the microvilli. All of these enzymes cleave the chemical bonds of macromolecules through hydrolysis, a reaction that adds a water molecule (see Figure 3.4B). Digestive enzymes are classified according to the substances they hydrolyze: **proteases** break the bonds between adjacent amino acids in proteins; **carbohydrases** hydrolyze carbohydrates; **peptidases** break down peptides; **lipases**, fats; and **nucleases**, nucleic acids. We will discuss the digestive enzymes of humans in detail in [Key Concept 50.3](#).

proteases Digestive enzymes that break the bonds between adjacent amino acids in proteins.

carbohydrases Digestive enzymes that hydrolyze carbohydrates.

peptidases Digestive enzymes that break down peptides.

lipases Digestive enzymes that break down fats.

nucleases Digestive enzymes that break down nucleic acids.

The gut microbiome contributes to digestion

The gut is colonized by a huge population of microorganisms, mostly bacteria. Collectively the foreign species associated with an organism are called its **microbiota**, and their cumulative genomes are called the organism's **microbiome**. The microbiomes of the skin are different from the microbiomes of the mouth, gut, respiratory tract, and urogenital tracts. The microbiota of the gut obtain their nutrition from the food passing through the gut while contributing to the host's digestive processes. For example, members of the leech genus *Hirudo* produce no enzymes that can digest the proteins in the blood they suck from vertebrates; instead they depend on bacteria to perform this service. The resulting amino acids are subsequently used by both the leech and the bacteria. The microbiota of the human gut also provide important services in digestion, prevent the establishment of harmful microorganisms, and even produce some vitamins (vitamin K and biotin). It is estimated that the human body consists of 10^{13} cells, but our guts contain probably ten times that number of unicellular organisms representing at least 500 different species (see [Figure 25.19](#)). Recent studies have revealed that gut microbiomes are not constant, but are influenced by diet and other factors, including medications we ingest. The effects of different microbiomes may go far beyond simply facilitating digestion ([Investigating Life: How Does the Gut Microbiome Contribute to Obesity and Metabolic Disease?](#)).

microbiota The diverse communities of bacteria that live on or within the body.

microbiome The diverse community of bacteria that lives on or within the body of an organism and is essential to bodily function.

How Does the Gut Microbiome Contribute to Obesity and Metabolic Disease

experiment

Original Paper: Caesar, R., V. Tremaroli, P. Kovatcheva-Datchary, P. D. Cani and F. Bäckhed. 2015. Crosstalk between gut microbiota and dietary lipids aggravates WAT inflammation through TLR signaling. *Cell* 162: 658–668.

Fats differ in fatty acid composition, and fatty acids differ in the number of single or double bonds between their carbon atoms (see Key Concept 3.4). Saturated fatty acids have no double bonds, and unsaturated fatty acids do. Diets rich in saturated fatty acids are implicated in several health concerns, but what is it about saturated fatty acids that is unhealthy? Recent research examines the effect of diet on the gut microbiome, and in turn, the effect of the microbiome on health. Does the amount of saturated fat in the diet influence the composition of the microbiome, and does the microbiome influence the health consequences of a diet rich in saturated fats? We examine the first question in the experiment below, and the second question in an optional online companion exercise.

HYPOTHESIS ▶ The type of fat in the diet can influence the composition of the gut microbiome.

METHOD

1. Raise two groups of 15 mice on isocaloric diets rich in saturated fats (lard) or unsaturated fats (fish oil).
2. Each week, record the mice's body weight.
3. At the end of 11 weeks, compare the mice's (1) microbiomes, by sequencing the ribosomal RNA genes, and (2) body weight gain.

CONCLUSIONS

1. The fat composition of the diet influenced the composition of the microbiome.
2. Mice on the diet containing saturated fats gained more weight and gained weight faster than mice on the isocaloric diet containing unsaturated fats.

RESULTS

work with the data

The researchers hypothesized that mice consuming more saturated fats will have a higher probability of becoming obese and developing symptoms of diabetes. To test for dietary effects on the development of metabolic disease, the researchers collected additional data from the two cohorts of mice: fasting blood glucose levels and fasting blood insulin levels. They also did an insulin tolerance test (effect of a dose of insulin on blood glucose level). Data are reported as means ($\pm$ SEM).

QUESTIONS

1. Using a *t*-test, determine whether the difference in the fasting blood glucose levels for the lard-fed and fish-oil-fed mice is significant.
2. Using a *t*-test, determine whether the difference in the fasting blood insulin levels for the lard-fed and fish-oil-fed mice is significant.
3. Plot the glucose over time data. Did the two groups of mice differ in their response to the same dose of insulin? At which time points?
4. What conclusions can you make about the effect of the type of dietary fat on carbohydrate metabolism?

A similar **work with the data** exercise may be assigned in **LaunchPad**.

Fasting blood glucose (mM)		Fasting blood insulin (ng/mL)	
Lard (<i>N</i> = 14)	Fish oil (<i>N</i> = 14)	Lard (<i>N</i> = 10)	Fish oil (<i>N</i> = 14)
11 (0.22)	10.32 (0.23)	3.96 (0.36)	1.09 (0.17)

Time after insulin injection (min)	Blood glucose (% of the time 0 level)	
	Lard	Fish oil
0	100	100
30	59.8 (3.05)	49.8 (4.09)
60	54.5 (3.51)	37.2 (4.07)
90	63.1 (3.91)	39.1 (4.09)
120	75.6 (3.06)	56.9 (3.31)

50.2 recap

Heterotrophs have diverse adaptations for acquiring food. Once captured or ingested, food is digested extracellularly by secreted enzymes to release nutrients that are absorbed into the animal's body, usually via a tubular gut. The gut microbiome plays a role in digestion.

learning outcomes

You should be able to:

- Compare the feeding and digestive adaptations of different species.
- Relate structural features of animal guts to their functions and adaptive significance in

digestion.

- Describe digestive enzymes that are present in animal guts.
 - Explain the importance of the microbiome in the digestion of food.
-

1. Why do herbivores typically spend more time feeding than do carnivores?
2. What do the actions of all digestive enzymes have in common?
3. Why is it common for individuals to have digestive problems after antibiotic therapy?
4. When people with celiac disease eat food containing gluten, their immune system damages their intestinal villi. If undiagnosed, such people are likely to experience bloating, abdominal pain, diarrhea, fatty stool, loss of body weight, and iron deficiency. Why do these symptoms occur?

Once ingested by an animal, food may be fragmented and moved into the gut for digestion by hydrolytic enzymes. The processes of digestion release nutrients that are absorbed into the animal's body. Next we will focus on how those processes occur in vertebrates.

50.3 The Vertebrate Gastrointestinal System Is a Disassembly Line

Digestion in vertebrates occurs in the gastrointestinal system, which includes a tubular gut running from mouth to anus and several accessory structures that produce secretions that play important roles in digestion (**Figure 50.9**). In this section we consider three important processes of this system: the movement of food through it, the sequential steps of digestion, and the absorption of nutrients. We use as our primary example a typical vertebrate, the human.

Figure 50.9 The Human Digestive System Different compartments in the long tubular gut specialize in digesting food, absorbing nutrients, and storing and expelling wastes. Accessory organs contribute secretions containing enzymes and other molecules.

focus your learning

The structure of the vertebrate gut supports its digestive function.

A variety of chemical and physical processes take place in different parts of the digestive system to efficiently break down food into forms that the body can use.

Herbivores do not produce the cellulases needed to digest cellulose in their plant diet, and thus require microbiota to carry out this task.

The vertebrate gut consists of concentric tissue layers

Tissues of the vertebrate gut are arranged in concentric layers that have a similar organization throughout its length (**Figure 50.10**). The **mucosa** lines the internal cavity, or **lumen**, of the gut. The mucosa consists of delicate epithelial cells with underlying connective tissue. Some cells of this mucosal epithelium secrete mucus to lubricate and protect the walls of the gut; some secrete digestive enzymes; and some secrete hormones. Mucosal epithelial cells in the stomach secrete hydrochloric acid, and as we noted in **Key Concept 50.1**, some secrete intrinsic factor to aid the absorption of vitamin B₁₂. In some regions of the gut, nutrients are absorbed by mucosal epithelial cells. The apical cell membranes of these absorptive cells have microvilli that increase the surface area over which absorption can take place (see **Figure 50.8C**).

mucosa The first layer of the gut that lines the luminal surface.

lumen (loo' men) [L. *lumen*: light] The open cavity inside any tubular organ or structure, such as the gut or a renal tubule.

Figure 50.10 Tissue Layers of the Vertebrate Gut The organization of tissue layers is the same in all compartments of the gut, but specialized adaptations of specific tissues characterize different regions.

At the base of the mucosa there is a thin layer of smooth muscle cells with random orientations. The function of this cell layer is to move the mucosal epithelium to maximize its contact with the gut contents. Just under the mucosa is the submucosal tissue layer where blood and lymph vessels pick up nutrients to transport to the rest of the body. The [submucosa](#) also contains a network of nerves; the neurons in this network have sensory functions (responsible for stomach aches) and also control various secretory functions of the gut.

submucosa (sub mew koe' sah) The tissue layer just under the epithelial lining of the lumen of the digestive tract.

External to the submucosa are two layers of smooth muscle responsible for large movements of the gut. Innermost is the circular muscle layer, with its cells oriented around the gut. Outermost is the longitudinal muscle layer, with its cells oriented along the length of the gut (see [Figure 50.10](#)). The circular muscles constrict the gut, and the longitudinal muscles shorten it. Between the two layers of smooth muscle is another nerve network that controls and coordinates the movements of the gut. The coordinated activity of the two smooth muscle layers mixes contents of the gut and moves it continuously toward the anus.

Nerve nets in the submucosa and between the smooth muscle layers are called the [enteric nervous system](#), and they are unusual. The cell bodies of most peripheral nerves are in the central nervous system (CNS)—in the brain or spinal cord. The only exceptions are the postganglionic cells of the autonomic nervous system and the cells of the enteric nervous system. In addition, most neurons of the peripheral nervous system either receive synapses from neurons in the CNS or contribute synapses to neurons in the CNS. In contrast, most of the neurons in the enteric nervous system form synapses only with other neurons in their network. Thus they are responsible for communication within the gut. The CNS can influence activity in the enteric nervous system and receive information from it, but the gut truly has “a mind of its own.”

enteric nervous system The nerve nets in the submucosa and between the smooth muscle layers of the vertebrate gut.

A tissue membrane called the [peritoneum](#) surrounds the gut and most of the organs of the abdominal cavity as well as lining the wall of the cavity. The peritoneum includes connective and epithelial tissues that secrete a lubricating fluid that enables the organs to easily slide against each other in the body cavity.

peritoneum The mesodermal lining of the body cavity in coelomate animals.

Gut motility moves food through the gut and aids digestion

In humans and most other mammals, food is chewed in the mouth and mixed with saliva. Periodically the tongue pushes a bolus (mass) of the chewed food toward the throat. By making contact with the soft palate at the back of the mouth cavity, the food bolus initiates swallowing, which is a complex series of reflexes. Swallowing propels the food through the pharynx (where the mouth cavity and nasal passages join) and into the [esophagus](#) (food tube). To prevent food

from entering the trachea (windpipe), the larynx (voice box) closes, and a flap of tissue called the **epiglottis** covers the entrance to the larynx (**Figure 50.11A**).

esophagus (i soff' i gus) [Gk. *oisophagos*: gullet] That part of the gut between the pharynx and the stomach.

epiglottis The flap of tissue that covers the entrance of the larynx to prevent food and liquid from entering the trachea.

Media Clip 50.1 **Following Food from Mouth to Gut** www.Life11e.com/mc50.1

Figure 50.11 Swallowing and Peristalsis (A) Food pushed to the back of the mouth triggers the swallowing reflex. **(B)** Once a food bolus enters the esophagus, peristalsis propels it from mouth to anus by coordinated actions of the circular and longitudinal muscle layers of the gut.

Once a bolus of food enters the esophagus, it is moved toward the stomach both by gravity and by waves of muscle contraction called **peristalsis** (**Figure 50.11B**). The muscle of the upper region of the esophagus is striated (i.e., skeletal muscle) and is controlled by the CNS reflexes of swallowing. The muscles of the rest of the esophagus are smooth muscles controlled by the autonomic and enteric nervous systems.

peristalsis (pair' i stall' sis) Wavelike muscular contractions proceeding along a tubular organ, propelling the contents along the tube.

Smooth muscles of the gut contract in response to being stretched (see **Figure 47.8**). When a bolus of food reaches the smooth muscle region of the esophagus and stretches it, the muscle responds by contracting, thus pushing food toward the stomach. Why doesn't the contraction of the esophageal smooth muscle push food back toward the mouth? The nerve net between the two smooth muscle layers coordinates the muscles so that when a region of the gut smooth muscle contracts, the circular smooth muscle just beyond it relaxes. This action, controlled by the enteric nervous system, is called an anticipatory wave of relaxation. The contractions of smooth muscles behind the relaxing area push food into it—in the direction of the anus. The resulting stretch of that region stimulates its circular smooth muscle to contract as the anticipatory wave of relaxation causes the smooth muscle of the next region to relax. The peristaltic waves of contraction and relaxation of the gut smooth muscle move food along the gut from the mouth to the anus.

At the junction of the esophagus and stomach is an esophageal **sphincter**, a ring of circular smooth muscle that is normally constricted. Waves of peristalsis cause the sphincter to relax enough to let food pass from the esophagus into the stomach. Sphincter muscles are found throughout the digestive tract: the pyloric sphincter governs the passage of stomach contents into the small intestine; the ileocaecal sphincter controls the flow of food between the small and large intestines; and the anal sphincter relaxes to allow defecation.

sphincter (sfink' ter) [Gk. *sphinkter*: something that binds tightly] A ring of muscle that can close an orifice, for example, at the anus.

Some movements of the stomach are not as coordinated as the peristaltic movements of the esophagus and serve to move the contents of the stomach around and mix them with the digestive juices. However, peristaltic waves of contraction reorganize in the lower region of the stomach and push the semidigested material up against the pyloric sphincter which controls the opening to the small intestine. In the small intestine, peristaltic activity continues to move the gut contents toward the large intestine.

Chemical digestion begins in the mouth and the stomach

Salivary glands secrete the enzyme amylase into the mouth where it is mixed with the food being chewed. Amylase hydrolyzes bonds between glucose monomers that make up carbohydrate molecules. The action of amylase is what makes a chewed piece of bread or cracker taste slightly sweet if you hold it in your mouth long enough.

The main role of the stomach is to store food and deliver it gradually to the small intestine so that digestion can occur more slowly than ingestion. The stomach produces secretions that facilitate digestion and also kill potential pathogens that are ingested with food. **Gastric pits** in the stomach walls (**Figure 50.12A and B**) have three types of secretory cells: (1) mucus secreting cells, (2) **parietal cells** that secrete hydrochloric acid (HCl), and (3) **chief cells** that secrete the inactive proteolytic enzyme pepsinogen (**Figure 50.12C**). The low pH of the stomach juices has multiple functions. It kills most microorganisms that are ingested with food; it denatures proteins, making them more accessible to the hydrolytic actions of pepsin; and it converts pepsinogen to pepsin by cleaving away a sequence of amino acids that masks the active site of the enzyme. Newly activated pepsin activates other pepsinogen molecules, creating a positive feedback process called **autocatalysis**. Acid and the proteolytic enzyme pepsin could damage the stomach walls, but the mucus-secreting cells provide a protective coating for the walls of the gastric pits and stomach.

gastric pits Deep infoldings in the walls of the stomach lined with secretory cells.

parietal cells One of three types of secretory cell found in the gastric pits of the stomach wall. Parietal cells produce hydrochloric acid (HCl), creating an acidic environment that destroys many of the harmful microorganisms ingested with food. (See chief cells.)

chief cells One of three types of secretory cell found in the gastric pits of the stomach wall. Chief cells secrete the protein-digesting enzyme pepsin. (See parietal cells.)

autocatalysis [Gk. *autos*: self + *kata*: to break down] A positive feedback process in which an activated enzyme acts on other inactive molecules of the same enzyme to activate them.

Figure 50.12 Action in the Stomach (A) The human stomach stores ingested food and mixes it with digestive secretions. (B) Gastric pits are folds in the stomach lining. (C) Parietal cells in the gastric pits secrete hydrochloric acid, and chief cells secrete pepsinogen. HCl and autocatalysis convert inactive pepsinogen into active pepsin. (D) Parietal cells create a tremendous H^+ concentration difference between the gut lumen and the extracellular fluid by actively transporting into the lumen of the gastric pit H^+ ions produced through the catalytic action of carbonic anhydrase.

The production of hydrochloric acid (HCl) by the parietal cells of the gastric pits is quite impressive. It amounts to about 2 liters per day—enough to bring the pH of the stomach contents below 1, which is the same as battery acid and ten times more acidic than pure lemon juice. This means that across their cell membranes, parietal cells create a H^+ ion concentration difference of 3 million-fold. Such a feat of transport is not seen anywhere else in the body. How do the gastric pits do it? Enzymes and transporters are involved.

The enzyme carbonic anhydrase in parietal cells catalyzes the hydration of CO_2 to H_2CO_3 , which dissociates into H^+ and bicarbonate ion (HCO_3^-). An antiporter transport protein (see [Figure 6.13](#)) exchanges HCO_3^- for Cl^- on the blood side of the gastric pits, and an antiporter on the gastric pit side exchanges H^+ for K^+ ([Figure 50.12D](#)). However, K^+ leaks out of the parietal cell down its concentration gradient. Thus the inward transport of K^+ acts like an endless conveyor belt moving H^+ out into the stomach lumen. Cl^- also passively leaks out of the gastric lumen side of the parietal cells to maintain electrical neutrality.

The stomach gradually releases its contents to the small intestine

The acidic, fluid mixture of gastric juice and partly digested food in the stomach is called [chyme](#). A few substances can be absorbed across the stomach wall, including alcohol (hence its rapid effects), aspirin, and caffeine, but even these substances are absorbed in rather small quantities

from the stomach; most absorption takes place in the small intestine. At the bottom of the stomach, peristaltic contractions push the chyme up against the pyloric sphincter. Associated waves of anticipatory relaxation cause the pyloric sphincter to relax briefly so that little squirts of chyme enter the small intestine. The human stomach empties gradually over a period of approximately 4 hours. This slow introduction of food into the small intestine enables it to work on a little material at a time.

chyme (kime) [Gk. *kymus*: juice] Created in the stomach; a mixture of ingested food with the digestive juices secreted by the salivary glands and the stomach lining.

Most chemical digestion occurs in the small intestine

In the [small intestine](#), digestion of carbohydrates and proteins continues, and digestion of fats and absorption of nutrients begin. The small intestine takes its name from its diameter; it is in fact a very large organ, about 6 meters long in an adult human. Given its length and the folds, villi, and microvilli of its epithelial cells, its inner surface area is roughly the size of a tennis court. Across this surface the small intestine absorbs the nutrient molecules derived from food.

small intestine The portion of the gut between the stomach and the colon; consists of the duodenum, the jejunum, and the ileum.

The small intestine of humans has three sections. The initial section (about 25 cm long) is called the [duodenum](#) and is the site of most digestion; the [jejunum](#) and the [ileum](#) (together about 600 cm) carry out 90 percent of the absorption of nutrients (see [Figure 50.9](#)).

duodenum (do' uh dee' num) The beginning portion of the vertebrate small intestine. (See *also* ileum, jejunum.)

jejunum (jih jew' num) The middle division of the small intestine, where most absorption of nutrients occurs. (See *also* duodenum, ileum.)

ileum The final segment of the small intestine. (See *also* duodenum, jejunum.)

Digestion in the small intestine involves many specialized enzymes, as well as several other secretions. Two accessory organs that are not part of the digestive tract—the liver and the pancreas — produce most of these secretions and deliver them to the lumen of the intestine through ducts.

LIVER

The liver synthesizes [bile](#) from cholesterol. Bile also includes other substances, such as phospholipids and bilirubin (the breakdown product of hemoglobin). Bile flows from the liver through the hepatic duct. A side branch off the hepatic duct called the cystic duct goes to the [gallbladder](#), where bile is stored. Below this junction, the hepatic duct is called the common bile duct. Before it reaches the duodenum, the common bile duct is joined by the pancreatic duct ([Figure 50.13](#)).

bile A secretion of the liver made up of bile salts synthesized from cholesterol, various phospholipids, and bilirubin (the breakdown product of hemoglobin). Emulsifies fats in the small intestine.

gallbladder In the human digestive system, an organ in which bile is stored.

Figure 50.13 Ducts of the Gallbladder and Pancreas Bile produced in the liver flows from the liver via the hepatic duct. Branching off this duct is the gallbladder, which stores bile. Below the gallbladder, the hepatic duct is called the common bile duct and is joined by the pancreatic duct before entering the duodenum.

Fat entering the duodenum stimulates cells of the duodenal epithelium to release the hormone **cholecystokinin (CCK)**, which stimulates the walls of the gallbladder to contract rhythmically. As a result, bile is squeezed out of the gallbladder and through the cystic duct to the common bile duct. Peristalsis moves the bile down the bile duct, and a small sphincter at the junction of the common bile duct with the duodenum relaxes in response to waves of peristalsis and allows squirts of bile to enter the duodenal lumen.

cholecystokinin (CCK) (ko' luh sis tuh kai' nin) A hormone produced and released by the lining of the duodenum when it is stimulated by undigested fats and proteins. It stimulates the gallbladder to release bile and slows stomach activity.

To understand the role of bile in fat digestion, think of an oil-and-vinegar salad dressing. Oil is hydrophobic and tends to aggregate in large globules. For that reason, many salad dressings include an emulsifier—something that prevents oil droplets from aggregating. Mayonnaise, for example, is oil and vinegar with egg yolk added as an emulsifier. Bile emulsifies fats in the chyme. One end of each bile molecule is lipophilic (soluble in fat), and the other end is hydrophilic (soluble in water). The lipophilic ends of bile molecules merge with the fat droplets,

leaving their hydrophilic ends sticking out. As a result, bile prevents small fat droplets from congealing together into large fat droplets, and thereby the surface area of the fats exposed to the fat-digesting enzymes (lipases) is greatly enlarged. The very small fat particles that result from emulsification by bile are called **micelles** (Figure 50.14A).

micelle A particle of lipid covered with bile salts that is produced in the duodenum and facilitates digestion and absorption of lipids.

Figure 50.14 Digesting Fats (A) Dietary fats are broken up by bile into small micelles that present a large surface area to lipases. **(B)** The products of fat digestion are absorbed by intestinal mucosal cells, where they are resynthesized into triglycerides and exported to lymphatic vessels.

Q: A small percentage of people who have had their gallbladders removed must thereafter eat a low-fat diet, or they will experience diarrhea. Why?

PANCREAS

The **pancreas** is a large gland that lies just behind and below the stomach (see [Figures 50.9](#) and [50.13](#)). It is both an endocrine gland (secreting hormones into the circulation; see [Key Concept 40.1](#)) and an exocrine gland (secreting digestive juices through the pancreatic duct to the gut lumen). The exocrine tissues of the pancreas produce a host of digestive enzymes, including lipases, amylases, proteases, and nucleases ([Table 50.3](#)). As in the stomach, the protease enzymes are released in inactive forms called **zymogens**; if proteases were not in this inactive state, they would digest the pancreas and its ducts before ever reaching the duodenum. Once in the duodenum, the zymogen trypsinogen is activated by the enzyme enterokinase (secreted by cells lining the duodenum) to produce the active protease **trypsin**. Trypsin cleaves other zymogens, releasing other proteases as well as more active trypsin.

pancreas (pan' cree us) A gland located near the stomach of vertebrates that secretes digestive enzymes into the small intestine and releases insulin into the bloodstream.

zymogen The inactive precursor of a digestive enzyme; secreted into the lumen of the gut, where a protease cleaves it to form the active enzyme.

trypsin A protein-digesting enzyme. Secreted by the pancreas in its inactive form (trypsinogen), it becomes active in the duodenum of the small intestine.

table 50.3 Major Digestive Enzymes of humans

Source/enzyme	Action
SALIVARY GLANDS	
Salivary amylase	Starch → Maltose
STOMACH	
Pepsin	Proteins → Peptides; autocatalysis
PANCREAS	
Pancreatic amylase	Starch → Maltose
Lipase	Fats → Fatty acids and glycerol
Nuclease	Nucleic acids → Nucleotides
Trypsin	Proteins → Peptides; zymogen activation
Chymotrypsin	Proteins → Peptides
Carboxypeptidase	Peptides → Shorter peptides and amino acids
SMALL INTESTINE	
Aminopeptidase	Peptides → Shorter peptides and amino acids
Dipeptidase	Dipeptides → Amino acids
Enterokinase	Trypsinogen → Trypsin
Nuclease	Nucleic acids → Nucleotides
Maltase	Maltose → Glucose
Lactase	Lactose → Galactose and glucose
Sucrase	Sucrose → Fructose and glucose

The mixture of zymogens produced by the pancreas can be dangerous if the pancreatic duct is blocked or if the pancreas is injured by infection or physical trauma such as a blow to the

abdomen. A few activated trypsin molecules can initiate a chain reaction of enzyme activity that digests the tissues of the pancreas (a condition called pancreatitis), destroying both its endocrine and exocrine functions.

The ducts of the pancreas produce a secretion rich in bicarbonate ions (HCO_3^-). Bicarbonate ions are alkaline (basic) and neutralize the acidic pH of the chyme that enters the duodenum from the stomach. Intestinal enzymes function best at a neutral or slightly alkaline pH. The production of bicarbonate and its secretion into the pancreatic ducts is similar to the production of H^+ ions and their secretion into the gastric pits—but with opposite spatial orientations. In both types of secretory cells, carbonic anhydrase catalyzes the hydration of CO_2 to produce H_2CO_3 that dissociates into H^+ and HCO_3^- ions. Whereas in the gastric pit the H^+ is secreted into the lumen of the pit, in the pancreatic duct it is the HCO_3^- that is secreted into the lumen, and the H^+ is transported into the circulation.

Nutrients are absorbed in the small intestine

The final step in digesting proteins and carbohydrates and absorbing their components occurs among the intestinal microvilli. Mucosal epithelial cells produce peptidases that cleave small peptides into absorbable amino acids. These epithelial cells also produce the enzymes maltase, lactase, and sucrase that cleave the common disaccharides into absorbable monosaccharides—glucose, galactose, and fructose. There is also some lipase activity for fat digestion.

Many humans stop producing the enzyme lactase in childhood and thereafter have difficulty digesting lactose (the sugar in milk). Lactose is a disaccharide and cannot be absorbed without being cleaved into its constituents, glucose and galactose. Unabsorbed lactose is metabolized by bacteria in the large intestine, causing gas, diarrhea, and abdominal cramps.

The mechanisms by which cells of the intestinal epithelium absorb nutrients and inorganic ions are diverse and include diffusion, facilitated diffusion, active transport, and secondary active transport. Many inorganic ions such as sodium, calcium, and iron are actively transported by these cells. For example, active Na^+ transporters exist on the basal and lateral sides of the epithelial cells. They maintain a low concentration of Na^+ in those cells so that Na^+ can diffuse in from the chyme in the intestinal lumen. About 30 grams of Na^+ are transported this way every day, and Cl^- follows.

The transport of Na^+ and other ions is important for water absorption because it creates an osmotic concentration gradient. At least 7-8 liters of water per day move through the spaces between the epithelial cells in response to this osmotic gradient. Because the water moves through spaces between the cells and not through the cells themselves, it can carry with it nutrients that are in solution — a transport mechanism called [solvent drag](#) or [bulk transport](#).

solvent drag Transport mechanism in which solutes move across a tissue layer through intercellular spaces by a flow of water (solvent).

bulk transport See solvent drag.

Many different kinds of transport proteins function in epithelial cell membranes. Some, such as the transport protein for fructose, only facilitate diffusion, and that requires a concentration gradient. Once fructose enters the cell it is converted to glucose, so the concentration of fructose in the cell is always low and the concentration gradient is maintained. Transport proteins known as symporters (see [Figure 6.13](#)) exploit the concentration gradient of Na^+ between the inside and outside of the cell that is maintained by the Na^+/K^+ pump common to all cells (see [Figure 6.14](#)). Symporters combine the transport of Na^+ and another molecule, such as glucose, galactose, or an amino acid. As Na^+ moves down its concentration gradient into the

cell, the “hitchhiking” molecules are carried along with it.

The absorption of the products of fat digestion is relatively simple. Triglycerides are hydrolyzed to diglycerides, monoglycerides, and fatty acids, all of which are lipid-soluble and thus able to pass through the cell membranes of the microvilli. In the intestinal epithelial cells, these molecules are resynthesized into triglycerides, combined with cholesterol and phospholipids, and coated with protein to form water-soluble **chylomicrons** (**Figure 50.14B**). Rather than enter the blood directly, chylomicrons pass into blind-ended lymph vessels called **lacteals** that are inside each villus (see **Figure 50.8C**). They then flow through the lymphatic system, entering the bloodstream through the thoracic ducts at the base of the neck. After a meal rich in fats, chylomicrons can be so abundant in the blood that they give the blood plasma a milky appearance. Chylomicrons deliver their triglyceride and cholesterol cargo as they circulate through tissues.

chylomicrons (ky low my' cron) Particles of lipid coated with protein, produced in the gut from dietary fats and secreted into the extracellular fluids.

lacteals The smallest vessels of the lymphatic system.

The bile molecules that emulsify fats are not absorbed along with the monoglycerides, diglycerides, and the fatty acids, but are shuttled back and forth between the gut contents and the microvilli. In the ileum, bile is actively reabsorbed and returned to the liver via the bloodstream.

Absorbed nutrients go to the liver

Blood leaving the digestive tract flows to the liver in the **hepatic portal vein**. This large vein delivers the blood to small spaces called sinusoids between groups of liver cells. These cells absorb the nutrients coming from the digestive tract and either store them or convert them to molecules the body needs. Glucose, galactose, and fructose are used to synthesize glycogen. Amino acids are used to build proteins. Lipids from the chylomicrons are either stored as triglycerides or used to make lipoproteins, which are released by the liver and carry the triglycerides and cholesterol to other tissues (as we will discuss in **Key Concept 50.4**).

hepatic portal vein The vein that begins in capillary beds in the gut and ends in capillary beds in the liver.

Water and ions are absorbed in the large intestine

The motility of the small intestine gradually pushes its contents through another sphincter—the ileocaecal sphincter—and into the large intestine, or **colon**. Most of the available nutrients have been removed from the chyme that enters the colon, but it contains a lot of water and inorganic ions. A major type of motility in the colon is called segmentation movements. These movements are mostly due to contractions of circular muscles that repeatedly divide the colon into separate segments. Functionally, segmentation movements cause the chyme to slosh around in the colon and promote absorption of ions and water by increasing contact between the chyme and the epithelium of the colon. As ions and water are absorbed, the chyme becomes a semisolid mass that forms feces. Absorption of too much water from the colon can cause hard feces and constipation. The opposite condition, diarrhea, results if too little water is absorbed. Excessive diarrhea caused by diseases such as cholera can produce such rapid loss of water and electrolytes that death can occur in hours. Simple rehydration therapy with electrolytes can save lives.

colon [Gk. *kolon*] The portion of the gut between the small intestine and the anus. Also called the large intestine.

Fecal matter is stored in the descending colon and in the rectum until defecation occurs. This is usually once a day and is preceded by strong peristaltic activity. The distension of the walls of the rectum by fecal matter initiates a parasympathetic reflex, causing the rectal muscle to contract and the internal anal sphincter to relax. In addition, there is an external anal sphincter that is under conscious control so that defecation is not entirely an involuntary act.

Herbivores rely on their microbiota to digest cellulose

Cellulose is the primary component of plant cell walls, and is therefore the principal component of the food of herbivores. Most herbivores, however, cannot produce cellulases, the enzymes that break down cellulose. (Exceptions include earthworms, shipworms, and the silverfish that eat books and stored papers.) From termites to cattle, herbivores rely on the microbiota of their digestive tracts to digest cellulose.

Ruminants (cud chewers) such as cattle ferment their plant-based food in special stomachs before digestion. Their stomachs are large, four-chambered organs (**Figure 50.15**). The first two chambers, the **rumen** and the **reticulum**, are packed with endosymbiotic microorganisms that break down cellulose by fermentation. The ruminant periodically regurgitates the contents of the rumen (the cud) into the mouth for more chewing. When swallowed again, the vegetal fibers present more surface area to the microorganisms. The microorganisms metabolize cellulose and other nutrients to simple fatty acids, which are nutrients for their host.

ruminant Herbivorous, cud-chewing mammals such as cows or sheep, characterized by a stomach that consists of four compartments: the rumen, reticulum, omasum, and abomasum.

rumen The first of the four chambers of the ruminant stomach. Along with the reticulum, it is where food is partially digested with the assistance of gut bacteria.

reticulum The second of the four chambers of the ruminant stomach. Along with the rumen, it is where food is partially digested with the assistance of gut bacteria.

Figure 50.15 A Ruminant's Stomach Bison, like their relatives domestic cattle, have a specialized stomach with four compartments that enables them to obtain energy from coarse plant material through bacterial fermentation of the otherwise indigestible plant material. The bacteria themselves become an important source of nutrition.

Q: Functionally, why do the rumen and reticulum come before the true stomach, the abomasum?

Enormous numbers of microorganisms leave the rumen along with the partially digested food. This mass is concentrated by water absorption in the **omasum** before it enters the true stomach, the **abomasum**, where the microorganisms are killed by secreted hydrochloric acid, partially digested by proteases, and passed on to the small intestine for further digestion and absorption. A cow derives more than 100 grams of protein per day from digestion of its microbiota. The rate of multiplication of microorganisms in the rumen offsets their loss, so a well-balanced, mutually beneficial relationship is maintained.

omasum The third of the four chambers of the stomach in ruminants; concentrates food by water absorption before it enters the true stomach (abomasum).

abomasum (a bo mey' sum) The fourth of the four chambers of the stomach in ruminants; the true stomach.

Some mammalian herbivores have a microbial fermentation chamber called a **cecum** extending from the large intestine. An example is the rabbit (see [Figure 50.7](#)). Since the cecum empties into the large intestine, absorption of nutrients produced by the microorganisms in the cecum is inefficient because of the limited surface area of the large intestine. Such species frequently produce two kinds of feces—ones that are pure waste and ones that contain cecal

material. In a behavior known as [coprophagy](#), these species reingest the cecal feces directly from the anus so they can digest and absorb the nutrients that would otherwise be lost. In humans the cecum is small and ends in the vestigial [appendix](#) which serves no digestive function.

cecum (see' cum) [L. blind] A blind branch off the large intestine. In many nonruminant mammals, the cecum contains a colony of microorganisms that contribute to the digestion of food.

coprophagy The consumption of feces.

appendix A small blind-end sac that is attached to the initial segment of the colon.

50.3 recap

The vertebrate gastrointestinal system is a tubular gut that is adapted to ingest food, fragment it, digest it, and absorb nutrients. Peristalsis moves food through the gut. Segmentation movements mix the gut contents. Enzymatic digestion followed by absorption of nutrients occur mostly in the small intestine; water and ions are absorbed in the large intestine.

learning outcomes

You should be able to:

- Explain the mechanisms that move food through the vertebrate digestive system.
- Describe the role of acid and how it is produced in the stomach.
- Discuss autocatalysis and its role in digestion.
- Explain how bile assists in digestion.
- Explain observations about the presence of microorganisms found in the digestive tracts of herbivores.
- Compare the roles of microbiota in the digestive systems of different vertebrates.

1. Explain why in the weightlessness of space, food still travels from the mouth to the stomach.
2. When some biochemists ground up a piece of stomach wall and stimulated it with the hormone that causes the stomach to secrete HCl, no change in the pH of the solution occurred. Why not?
3. How does bile assist in the digestion of fats, and why aren't equivalent molecules necessary to facilitate transport of lipids in the lymph and blood?
4. Explain why the gut microbiota is a significant source of nutrition for ruminants but not for humans.
5. Explain why in the ruminant digestive system HCl is secreted in the abomasum but not in the rumen, the reticulum, or the omasum.
6. Why would the autocatalytic property of pepsin foster a positive feedback mechanism of protein hydrolysis in the stomach?

The steps included in the ingestion and digestion of food—from fragmentation in the mouth to the digestive processes in the stomach and intestines—make the nutrients in food available for absorption and ultimately for metabolism. We will look next at how the processes of digestion are controlled and how nutrients are handled by the body once food has been digested.

50.4 Nutrient Availability Is Controlled and Regulated

As we indicated earlier, the vertebrate gut is a disassembly line, and as with a standard assembly line, the control and coordination of the sequential processes of digestion are critical. Both neuronal and hormonal controls govern these processes. Once the products of digestion are absorbed, their availability to the cells of the body must also be controlled and regulated.

focus your learning

Hormones control actions of the digestive tract and its accessory organs.

The liver interconverts and stores fuel molecules.

The liver controls fat metabolism through its production of lipoproteins, which move fats between storage and production sites.

The pancreas secretes hormones that help control glucose levels in the blood.

Body mass and food intake behavior are influenced by stimulatory and inhibitory hormones that activate neurons in the arcuate nucleus region of the hypothalamus in the brain.

Your salivation at the sight or smell of food is an autonomic reflex, as is swallowing. Other autonomic reflexes include the release of digestive juices and increased stomach motility stimulated by good food smells, as well as gagging at the smell of rotting meat. These reflexes are called the “cephalic phase” of control of digestive processes because they involve the CNS. Most of the control of digestive processes, however, involves neural and hormonal mechanisms that are intrinsic to the gut.

Neuronal messages travel from one region of the digestive tract to another in the enteric nervous system. One function of the gut’s nervous system is coordinating the movement of food through the gut. Of course, this intrinsic nervous system communicates information to the CNS and receives input from the CNS, but its most important role is to coordinate actions throughout the digestive tract. In spite of this marvelous intrinsic nervous system, however, much of the control and regulation of the digestive system and nutrient management involves hormonal mechanisms.

Hormones control many digestive functions

Several hormones control the activities of the digestive tract and its accessory organs (**Figure 50.16**). The first hormone ever discovered came from the duodenum; it was called **secretin** because it causes the pancreas to secrete digestive juices. We now know that secretin is only one of several hormones that control pancreatic secretion; specifically, secretin stimulates the cells of the pancreatic ducts to secrete a solution rich in bicarbonate ions.

secretin (si kreet' in) A peptide hormone secreted by the upper region of the small intestine when acidic chyme is present. Stimulates the pancreatic duct to secrete bicarbonate ions.

Figure 50.16 Hormones Control Digestion The hormones gastrin, cholecystokinin (CCK), and secretin are involved in feedback loops that control the sequential processing of food in the digestive tract. Red lines indicate inhibitory actions; green lines indicate stimulatory actions.

Q: Why do secretin and CCK stimulate the pancreas but inhibit the stomach?

The stimulus that causes the duodenum to release secretin is low pH caused by the arrival of acidic chyme from the stomach. Similarly, the presence of fats and proteins in the chyme stimulates the release of cholecystokinin (CCK), the hormone that stimulates the gallbladder to release bile. CCK also stimulates the pancreas to release digestive enzymes. Both CCK and secretin also have negative feedback effects on the stomach. They slow the movements of the stomach, thus slowing the delivery of chyme into the small intestine and allowing more complete

digestion in the duodenum.

The presence of food in the stomach stimulates cells in the lower region of the stomach to secrete a hormone called gastrin. Gastrin returns to the stomach in the blood and stimulates the secretion of digestive juices and also increases the motility of the stomach. Gastrin release begins to be inhibited when the pH of the stomach contents falls below 3—another example of negative feedback.

The liver stores and releases the molecules that fuel metabolism

Most animals do not eat continuously, so they can be either in an [absorptive](#) state (food in the gut) or in a [postabsorptive state](#) (no food in the gut). Nutrient requirements for energy metabolism and biosynthesis are continuous, however. Thus nutrient traffic must be controlled so that reserves accumulate in the liver, muscle, and adipose (fat) tissue while the animal is in the absorptive state and are then used efficiently during the postabsorptive state. When fuel molecules are abundant in the blood, the liver stores them in the form of glycogen and fats. The liver also synthesizes blood plasma proteins from circulating amino acids. When levels of fuel molecules in the blood decline, the liver taps its reserves and delivers nutrients into the blood.

absorptive state State in which food is in the gut and nutrients are being absorbed. (Contrast with postabsorptive state.)

postabsorptive state State in which no food remains in the gut and thus no nutrients are being absorbed. (Contrast with absorptive state.)

The liver has an enormous capacity to interconvert fuel molecules. Liver cells convert monosaccharides into either glycogen or fats during the absorptive state and then can reverse the process, returning glucose to the blood during the postabsorptive state. The liver can also convert certain amino acids and some other molecules, such as pyruvate and lactate, into glucose—the process of gluconeogenesis (see [Figure 9.14](#)). Gluconeogenesis provides an indirect pathway for exercising muscle to contribute to blood glucose levels. At high levels of aerobic activity, muscle cells break down their stores of glycogen to provide glucose for metabolic fuel. The glucose released from muscle glycogen, however, has to be used in the cells that produce it. Glucose cannot leave muscle cells as it can leave liver cells. However, when the activity of the muscle becomes anaerobic, pyruvate and lactate build up, leave muscle cells, and enter the circulation. Circulating pyruvate and lactate are taken up by the liver and converted to glucose that can then move out of the liver cells, circulate in the blood, and be taken up by muscle cells.

The liver produces lipoproteins: the good, the bad, and the ugly

The liver is the major controller of fat metabolism through its production of lipoproteins. A [lipoprotein](#) is a particle made up of a core of hydrophobic fat and cholesterol with a covering of hydrophilic protein that allows it to be suspended in water. Lipoproteins are the most abundant fuel reserve in the body, and they move fats from sites of absorption or synthesis to sites of storage, and from sites of storage to sites of use. You saw in [Key Concept 50.3](#) how bile in the intestine solves the problem of processing hydrophobic fats in an aqueous medium. Transport of fats in the circulatory system presents the same problem, and lipoproteins provide the solution.

lipoproteins Lipids packaged inside a covering of protein so that they can be circulated in the blood.

The chylomicrons produced by the mucosal cells of the intestine are the largest lipoprotein particles in the blood. As the circulation carries chylomicrons through muscle, adipose tissue, and liver, lipoprotein lipases attached to the endothelial cells of capillaries break down the chylomicrons' triglycerides so that the component fatty acids, monoglycerides, and glycerol can be taken up by the cells. The chylomicron remnants have lipid cores with a lot of cholesterol, and they are taken up by liver cells.

Lipoproteins different from chylomicrons are synthesized in the liver. These lipoproteins can be classified according to their density. Fat has a low density (it floats on water) and protein has a high density, so the greater the fat-to-protein ratio in the lipoprotein, the lower its density.

High-density lipoproteins (HDLs) transport lipids and cholesterol from tissues to the liver where the cholesterol can be used to synthesize bile. HDL consists of about 50 percent protein, 35 percent lipids, and 15 percent cholesterol. These are the “good” lipoproteins, and their levels are higher in people who exercise and are fit.

high-density lipoproteins (HDLs) Lipoproteins that remove cholesterol from tissues and carry it to the liver; HDLs are the “good” lipoproteins associated with good cardiovascular health.

Low-density lipoproteins (LDLs) transport cholesterol around the body for use in biosynthesis and for storage. LDL consists of about 25 percent protein, 25 percent lipids, and 50 percent cholesterol. These are the “bad” lipoproteins associated with a high risk for cardiovascular disease.

low-density lipoproteins (LDLs) Lipoproteins that transport cholesterol around the body for use in biosynthesis and for storage; LDLs are the “bad” lipoproteins associated with a high risk of cardiovascular disease.

Very low-density lipoproteins (VLDLs) contain mostly triglycerides, which are taken up by fat cells in adipose tissues around the body. VLDL consists of about 2 percent protein, 94 percent lipids, and 3 percent cholesterol. These are the “ugly” lipoproteins, as they are associated with obesity and diabetes as well as a high risk for cardiovascular disease.

very low-density lipoproteins (VLDLs) Lipoproteins that consist mainly of triglyceride fats, which they transport to fat cells in adipose tissues throughout the body; associated with excessive fat deposition and high risk for cardiovascular disease.

Insulin and glucagon control fuel metabolism

During the absorptive state, blood glucose levels rise as carbohydrates are digested and absorbed (**Focus: Key Figure 50.17**). During this time, the pancreas releases the hormone **insulin** which plays a major role in directing glucose to where it will be used or stored. In **Key Concept 50.3** we mentioned that the pancreas has both an exocrine function (secretions involved in digestion) and endocrine functions. The endocrine functions are located in clusters of cells in the pancreas called the islets of Langerhans. One class of islet cells, the beta cells, produces and releases insulin. Another class, the alpha cells, produces and releases the hormone **glucagon** (discussed below). The actions of insulin vary in different tissues, but they are all aimed at promoting the use of glucose for metabolic fuel and directing the excess glucose into storage as either glycogen or fat.

insulin (in' su lin) [L. *insula*: island] A hormone synthesized in islet cells of the pancreas that

promotes the conversion of glucose into the storage material, glycogen.

glucagon Hormone produced by alpha cells of the pancreatic islets of Langerhans. Glucagon stimulates the liver to break down glycogen and release glucose into the circulation.

focus: key figure

Figure 50.17 Regulating Glucose Levels in the Blood The hormone insulin (blue) acts to promote glucose utilization and storage and thereby lower blood glucose. The hormone glucagon (brown) acts on the liver to breakdown glycogen and release glucose into the blood.

Q: The nervous system depends on a constant supply of glucose, yet none of the actions of insulin or glucagon in this figure refer to supplying glucose to the nervous system.

Why?

Animation 50.2 Insulin and Glucose Regulation www.Life11e.com/a50.2

Glucose enters cells by diffusion. This diffusion is facilitated by transporters, but they are not active transporters—they require a concentration gradient, which is why it is important to regulate blood glucose levels so there is always an adequate glucose concentration gradient across the cell membranes. There are several kinds of glucose transporters, and those in skeletal muscle and adipose tissues are normally sequestered in cytoplasmic vesicles until insulin binds its receptors on the cell surface and triggers the insertion of transporters into the cell membrane.

Insulin plays many roles in controlling how cells use the glucose they take up from the circulation. In adipose cells, insulin inhibits lipase and promotes fat synthesis from glucose. In the liver, insulin activates an enzyme, glucokinase, that phosphorylates glucose as it enters the liver cell so it cannot diffuse back out again, thereby enhancing the overall diffusion of glucose into the cells. At the same time, insulin inhibits the enzyme glucose phosphatase that enables glucose to leave the cell. Insulin also activates glycogen synthase, an enzyme in liver cells that catalyzes the incorporation of glucose into glycogen, and activates enzymes that increase the flow of glucose into glycolysis (**Figure 50.18**).

Figure 50.18 Insulin Controls Glucose Traffic in the Liver Glucose freely enters and leaves liver cells by diffusion. But, when insulin is present (green arrows), glucose is phosphorylated and cannot leave the cell. The glucose 6-phosphate either enters glycolysis or is synthesized into glycogen. Insulin activates the enzymes of glycogen synthesis. Without insulin (red arrows) glucokinase is inhibited and glycogen phosphorylase and glucose phosphatase are activated. Thus glycogen is broken down to glucose phosphate, which is dephosphorylated so that it can leave the cell and enter the blood. Other monosaccharides—galactose and fructose—can also

diffuse into the cell and be converted to glucose through these pathways.

To maintain blood glucose levels during the postabsorptive state, liver cells break down their stored glycogen, releasing glucose into the blood. The multiple processes that make it possible for the liver to release glucose depend on a fall in blood insulin levels (see [Figure 50.18](#)). Falling insulin inhibits the enzyme responsible for glycogen synthesis and activates the enzyme that breaks down glycogen. Also, with less insulin, the enzyme that phosphorylates glucose is inhibited and activity of glucose phosphatase is increased. The result is a breakdown of glycogen and the return of glucose to the blood. Another consequence of the fall in insulin levels is the increased activity of lipases in the liver and adipose tissue, releasing fatty acids to the blood. Most cells preferentially use fatty acids as their metabolic fuel during the postabsorptive state. *Overall, the most important control of fuel metabolism in the postabsorptive state is the lack of insulin.*

One tissue that does not switch fuel sources when an animal is postabsorptive is the nervous system. The cells of the nervous system require a constant supply of glucose and can use other fuels only to a very limited extent. Most neurons do not require insulin to absorb glucose from the blood, but they do need an adequate glucose concentration gradient to drive the facilitated diffusion of glucose across their cell membranes. Therefore it is critical that blood glucose levels are maintained when an animal is postabsorptive. The overall dependence of neural tissues on glucose, and their requirement for constant blood glucose levels, are the reasons it is so important for other cells of the body to shift to fat metabolism during the postabsorptive state.

The metabolism of fuel molecules during the postabsorptive state is mostly controlled by the lack of insulin, but if blood glucose falls below a certain level, glucagon is released. Glucagon's effect is opposite that of insulin: it stimulates liver cells to break down glycogen and to carry out gluconeogenesis. Thus, under the influence of glucagon, the liver produces glucose and releases it into the blood. Note that under conditions that stimulate glucagon release, the effects of low insulin are already in play—low glycogen synthase activity, low glucokinase activity, and high glucose phosphatase activity.

The brain plays a major role in regulating food intake

Multiple brain areas and signals are involved in the regulation of food intake. Long ago it was discovered that damaging a region in the center of the rat hypothalamus resulted in the rats increasing their food intake and becoming obese. Damage to the lateral hypothalamus, however, led to decreased food intake and the rats became thin. In both cases the rats eventually reached a new equilibrium body weight; thus it appeared that a capacity for regulation remained, but the set point was altered.

We now know that another region of the hypothalamus, the [arcuate nucleus](#), plays an important role in integrating a variety of feedback signals that influence food intake and body mass. Cells within the arcuate nucleus send axons to the ventromedial and dorsal hypothalamus, as well as to other brain areas that influence food intake and metabolism. One group of arcuate neurons projects to brain areas that inhibit food intake, while the other projects to brain areas that stimulate food intake. But what stimulates or inhibits the activity of the arcuate neurons?

arcuate nucleus A group of neurons in the hypothalamus that produce and secrete many neuroendocrines and are involved in regulation of appetite.

Several factors have been identified that reflect the body's energy balance. Three of these are the proteins insulin, leptin, and ghrelin. Insulin, as detailed earlier, is released when blood glucose levels are high, and it induces a decline in food intake. [Leptin](#) (Greek *leptos*, "thin") is released by fat cells in proportion to how much lipid they contain. Evidence that leptin is a satiety

signal is described in [Figure 50.19](#). [Ghrelin](#) is released by the stomach when it is empty; its levels rise before meals and fall after meals. In the arcuate nucleus, insulin and leptin activate the neurons that inhibit feeding and inhibit the neurons that stimulate feeding. Ghrelin has the opposite effect on these two groups of neurons.

leptin A hormone produced by fat cells that is believed to provide feedback information to the brain about the status of the body's fat reserves.

ghrelin A hormone produced and secreted by cells in the stomach that stimulates appetite.

Figure 50.19 A Single-Gene Mutation Leads to Obesity in Mice

Original Papers: Coleman, D. L. 1973. Effects of parabiosis of obese with diabetes and normal mice. *Diabetologia* 9: 294–297.

Coleman, D. L. and K. P. Hummel. 1969. Effects of parabiosis of normal with genetically diabetic mice. *American Journal of Physiology* 217: 1298–1304.

In mice the *Ob* gene codes for the protein leptin, a satiety factor that signals the brain when enough food has been consumed. The recessive *ob* allele is a loss-of-function allele, so *ob/ob* mice do not produce leptin; they do not experience satiety and become obese. The *D* gene encodes the leptin receptor, so mice homozygous for the recessive loss-of-function allele *db*, even if they produce leptin, cannot use it and so become obese.

HYPOTHESIS ▶ Mice that cannot produce the satiety signal protein leptin will not become obese if they are able to obtain leptin from an outside source.

METHOD

1. Create two strains of genetically obese laboratory mice, one that lacks functional leptin (genotype *ob/ob*) and one that lacks the receptor for leptin (genotype *db/db*).
2. Create parabiotic pairs by surgically joining the circulatory systems of a non-obese (wild-type) mouse with a partner from one of the obese strains.
3. Allow mice to feed at will.

Parabiotic pair

Wild-type mouse (*Ob*^{+/+} and *Db*^{+/+}) Genetically obese mouse (either *ob/ob* or *db/db*)

RESULTS

Parabiotic *ob/ob* mice obtain leptin from the wild-type (WT) partner and lose fat. Parabiotic *db/db* mice remain obese because they lack the leptin receptor and thus the leptin they obtain from their partner has no effect.

CONCLUSION ▶ The protein leptin is a satiety signal that acts to prevent overeating and resultant obesity.

An integrative signal that could be playing a central role in regulation of feeding is the enzyme AMP-activated protein kinase (AMPK). When most cells are nutrient deprived, they produce AMPK, which stimulates the oxidation of substrates to replenish ATP. Fasting increases AMPK levels in the hypothalamus, and feeding reduces them. Insulin and leptin decrease AMPK activity in the hypothalamus, and ghrelin increases it. Thus AMPK could be a common pathway for various signals controlling food intake.

50.4 recap

The major factors controlling gut function are autonomic reflexes, the enteric nervous system, and the hormones gastrin, secretin, and cholecystokinin. Insulin is the major hormonal controller of fuel metabolism through its effects on liver, muscle, and adipose tissues. The hypothalamus controls food intake by generating sensations of hunger and satiety influenced by feedback from blood glucose and hormones, including insulin, leptin, and ghrelin.

learning outcomes

You should be able to:

- Explain how hormones control the rate of delivery of substrate to the small intestine and the appropriate secretions of digestive juices.
- Describe metabolic interconversions that take place in liver and muscle to meet the body's demands for glucose.
- Differentiate between the classes of lipoproteins.
- Compare the effects of insulin on activities in skeletal muscle cells, adipose cells, and liver cells.
- Cite evidence that supports the role of leptin as a satiety signal and ghrelin as a hunger signal.
- Interpret results from experiments designed to elucidate the mechanisms underlying regulation of body mass and food intake behaviors.

1. For various reasons patients may be fed through a tube going into their stomachs or tubes going all the way to their jejunum, the middle region of their small intestines. How would the feeding formulas used in the jejunal tube have to differ from the one applied through the gastric tube?
2. How do the three classes of lipoproteins differ in structure and function?
3. How are the effects of high and low insulin levels the same and different in liver and muscle?
4. In the experiments in which the lateral or the ventromedial hypothalamus was lesioned, what result enabled the conclusion that the regulation of body mass was altered rather than just the ability to produce satiety or hunger by the nutritional state of the body?
5. When exercising muscles do not have an adequate supply of oxygen, they continue to produce small amounts of ATP through glycolysis, but they also produce pyruvate and

lactate. Explain how this pyruvate and lactate can help support continuing glycolysis.

6. What evidence supports the hypothesis that leptin influences satiety?

investigatinglife

QA If the nutritional values were the same, could different foods have different impacts on health?

The Pima of Arizona were among the first communities to be examined with a genome-wide survey. Many candidate genes were shown to be associated with obesity, but weakly so. The conclusion was that there are genetic contributions to the propensity to develop obesity, but except for a few rare cases, obesity is a multigenic trait that is highly influenced by environment. One aspect of the environment is physical activity, but another one is diet. The caloric content of the diet is obviously an important factor, but what about the composition of the diet? The experiments described in *Investigating Life: How Does the Gut Microbiome contribute to Obesity and Metabolic Disease?* show that the composition of the diet can influence the composition of the gut microbiome, and the gut microbiome can influence the nutritional and other health effects of the diet. Thus, apart from differences in caloric intake, the consequences of the Pima switching from a traditional diet to a high-fat Western diet could have resulted in changes in their microbiomes that have contributed to obesity and diabetes.

Future directions

It would be of interest to compare the microbiomes of the Arizona and the Mexican Pima peoples, and to compare those with the microbiomes of other populations on similar and different diets. If a particular microbiome profile is associated with the obesity-diabetes phenotype, it might be possible to change that microbiome through dietary change to promote better health. Just as we now do genomic screening to identify health risks, we might consider microbiome screening. Whereas we cannot change our genetic makeup, we could change our microbiome either through diet, or even therapeutically by uses of antibiotics and microbiome transplants. A new branch of medicine could develop around the testing, diagnosis, and therapy of the gut microbiome.

► 50.1 Food Provides Energy As Well As Materials for Biosynthesis

- Animals are **heterotrophs** that derive their energy and molecular building blocks, directly or indirectly, from **autotrophs**.
- Carbohydrates, fats, and proteins in food supply animals with energy. A measure of the energy content of food is the **kilocalorie (kcal)**. Excess caloric intake is stored as glycogen and fat. **Review Figure 50.2**
- For many animals, food provides essential **carbon skeletons** that they cannot synthesize themselves. **Review Figure 50.4**
- Most researchers consider 8 amino acids to be essential for adult humans; some believe that infants require as many as 12 **essential amino acids** in their diet. **Macronutrients** are mineral elements needed in large quantities; **micronutrients** are needed in small amounts. **Review Figure 50.5, Table 50.1, Activity 50.1**
- **Vitamins** are organic molecules that must be obtained in food. **Review Figure 50.5 Table 50.2, Activity 50.2**
- **Malnutrition** results when any essential nutrient is lacking from the diet. Chronic malnutrition causes deficiency disease.

► 50.2 Diverse Adaptations Support Ingestion and Digestion of Food

- Animals can be characterized by how they acquire nutrients: **saprobies** and **detritivores**, or **decomposers**, depend on dead organic matter, filter feeders strain the aquatic environment for small food items, **herbivores** eat plants, and **carnivores** eat other animals. Behavioral and anatomical adaptations reflect these feeding strategies. See **Activity 50.3**
- Digestion involves the breakdown of complex food molecules into monomers that can be absorbed and used by cells. In most animals, digestion takes place in a tubular gut. **Review Figure 50.7**
- Absorptive areas of the vertebrate gut are characterized by a large surface area produced by extensive folding and numerous **villi** and **microvilli**. **Review Figure 50.8**
- Hydrolytic enzymes break down proteins, carbohydrates, and fats into their monomeric units.
- The microbiome of the gut participates in digestive processes, makes certain nutrients available for absorption, and is sensitive to composition of diet, ingestion of drugs, and other factors. **Review Investigating Life: How Does the Gut Microbiome Contribute to Obesity and Metabolic Disease?**

► 50.3 The Vertebrate Gastrointestinal System Is a Disassembly Line

- The vertebrate gut can be divided into several compartments with different functions. **Review Figure 50.9, Activity 50.4**
- The cells and tissues of the vertebrate gut are organized in the same way throughout its length. The innermost tissue layer, the **mucosa**, is the secretory and absorptive surface. The **submucosa** contains blood and lymph vessels and a nerve network that is sensory

and also controls gut secretions. External to the submucosa are two smooth muscle layers. Between the two muscle layers is another nerve network that controls the movements of the gut. **Review Figure 50.10**

- Swallowing is a reflex that pushes a bolus of food into the **esophagus**. **Peristalsis** and segmentation movements of the gut move the bolus down the esophagus and through the entire length of the gut. **Sphincters** block the gut at certain locations, but they relax as a wave of peristalsis approaches. **Review Figure 50.11**
- Digestion begins in the mouth, where amylase is secreted with the saliva. Digestion of protein begins in the **stomach**, where parietal cells secrete HCl and chief cells secrete pepsinogen, which becomes pepsin when activated by low pH and autocatalysis. The mucosa also secretes mucus, which protects the tissues of the gut. **Review Figure 50.12**
- In the **duodenum**, pancreatic enzymes carry out most of the digestion of food. **Bile** from the liver and **gallbladder** emulsifies fats into **micelles**. Bicarbonate ions from the **pancreas** neutralize the pH of the **chyme** entering from the stomach, thereby producing an environment conducive to the actions of pancreatic enzymes such as **trypsin**. **Review Figure 50.13, Table 50.3?**
- Final enzymatic cleavage of polypeptides and disaccharides occurs among the microvilli of the intestinal mucosa. Amino acids, monosaccharides, and inorganic ions are absorbed by the microvilli. Specific transport proteins are sometimes involved. Symporters often power the absorption of nutrients.
- Fats broken down by **lipases** are absorbed mostly as monoglycerides and fatty acids and are resynthesized into triglycerides within the gut epithelium. The triglycerides are combined with cholesterol and phospholipids and coated with protein to form **chylomicrons**, which pass out of the mucosal cells and into lymphatic vessels in the submucosa. **Review Figure 50.14, Animation 50.1**
- Water and ions are absorbed in the large intestine as waste matter and consolidated into **feces**, which are periodically eliminated.
- Microorganisms in some compartments of the gut digest materials that their host cannot. **Review Figure 50.15**

► 50.4 Nutrient Availability Is Controlled and Regulated

- Autonomic reflexes coordinate activity of the digestive tract, which has an intrinsic nervous system that can act independently of the CNS.
- The actions of the stomach and small intestine are largely controlled by the hormones **gastrin**, **secretin**, and **cholecystokinin (CCK)**. **Review Figure 50.16**
- The liver plays a central role in directing the storage and release of fuel molecules. In the **absorptive state**, the liver takes up and stores fats and carbohydrates, converting monosaccharides to glycogen or fats. The liver also takes up amino acids and uses them to produce blood plasma proteins, and can engage in gluconeogenesis.
- Fat and cholesterol are shipped out of the liver as **low-density lipoproteins (LDLs)**. **High-density lipoproteins (HDLs)** act as acceptors of cholesterol and bring fat and cholesterol back to the liver.
- **Insulin** largely controls fuel metabolism during the absorptive state and promotes glucose uptake as well as glycogen and fat synthesis. In the **postabsorptive state**, lack of insulin blocks the uptake and use of glucose by most cells of the body except neurons. If blood glucose levels fall, **glucagon** secretion increases, stimulating the liver to break down glycogen and release glucose to the blood. **Review Focus: Key Figure 50.17, Figure 50.18, Animation 50.2**

insulin (in' su lin) [L. *insula*: island] A hormone synthesized in islet cells of the pancreas that promotes the conversion of glucose into the storage material, glycogen.

- Food intake is governed by sensations of hunger and satiety, which are determined by brain mechanisms responding to feedback signals such as insulin, **leptin**, and **ghrelin**. Review [Figure 50.19](#), [Activity 50.5](#)

Original Paper: Sommer, F. et al. 2016. The gut microbiota modulates energy metabolism in the hibernating brown bear *Ursus arctos*. *Cell Reports* 14: 1655-1661.

Winter in the Northern Hemisphere can be a harsh period of low temperatures, deep snow cover, and limited food. The brown bear (*Ursus arctos*) survives the winter by hibernating. Bears do not eat during hibernation; but prior to the onset of winter, they overeat—and can double their body mass. The extra calories stored in their bodies as fat provide the necessary energy to sustain them through the winter months.

In recent years, information has been accumulating about the importance of the gut microbiota in the digestion of food and in many other aspects of nutrition. Researchers asked whether the gut microbiome of the bear was different when the bear was fattening and when it was fasting. They studied blood and fecal samples from 16 free-ranging brown bears during hibernation (February or March) and following hibernation (June). Fecal samples were analyzed for composition of the microbe communities, and the blood was tested for triglycerides and other nutrients. The results shown in [Figure A](#) show that there are differences in the composition of the microbiome and in blood levels of triglycerides, lactate, and succinate between summer and winter. Data on the composition of the microbiome are presented as the means, the twenty-fifth to seventy-fifth percentiles of the data (colored bars), and the total range of the data (vertical lines). The graphs on blood levels of nutrients are presented as the means $\pm$ 1 SEM (* = $P < 0.05$; ** = $P < 0.01$).

Figure A

The observed seasonal differences in the microbiota could result simply from the presence or absence of food in the gut. To test whether summer and winter microbiota could have different influences on nutritional status, the researchers examined the effects of these microbiota when introduced into germ-free mice. Germ-free mice have no gut microbiota and do not gain mass when placed on a high-fat diet, as normal mice do. Germ-free mice were given fecal transplants from summer or winter bears. Two weeks after the transplants, the mice were analyzed for changes in body mass, fat content, and blood triglyceride levels. The results are shown in [Figure B](#). Data are presented as means $\pm$ SEM (* = $P < 0.05$).

Figure B

Questions

1. How do the data on seasonal changes in blood triglycerides, lactate, and succinate indicate changes in the bears' metabolism between summer and winter? (Keep in mind that lactate is a product of glycolysis, and succinate is a citric acid cycle intermediate.)
2. Do the data indicate significant seasonal changes in the gut microbiome of the bears? Propose hypotheses that would help explain any changes.
3. What do the data indicate about how the energy balance of the germ-free mice is influenced when they are infected with microbes isolated from hibernating bears? Is there a difference between the outcomes from summer versus winter microbiota? Construct a hypothesis that explains your answer.
4. Taken together, what do all of these data suggest about digestive adaptations of brown bears that aid their survival in their native habitat?

Salt and Water Balance and Nitrogen Excretion

The vampire bat (*Desmodus rotundus*) is able to adjust its excretory physiology rapidly from water-excreting to water-conserving, depending on whether it is ingesting or digesting its blood meal.

How Vampire Bats Use Blood as Fast Food

Blood, sweat, and tears have the composition of extracellular fluid and taste salty. The composition and volume of the extracellular fluid are regulated by the excretory system. The challenges to an animal's excretory system depend on its environment and lifestyle. Some desert animals rarely encounter free water, so they must conserve water by excreting their excess ions and nitrogenous wastes with as little water loss as possible. Animals living in fresh water have the opposite challenge: water continuously enters their bodies by osmosis and with their food, so they must excrete water and conserve ions. Vertebrate animals living in the ocean face a challenge similar to that of the desert dwellers; they lose body water by osmosis and therefore need to conserve water and excrete ions.

The physiological mechanisms animals have to maintain salt and water balance are similar, but they are used in different ways to solve the problems unique to each species. Consider vampire bats, which feed on the blood of animals such as goats and cattle. The bats use their sharp incisor teeth to make a small incision (usually on the ankle or leg of a sleeping victim) and then lap up the blood. A vampire bat feeds only once a day, and has to do so quickly, before the victim awakens and shakes it off.

Blood contains nutritious protein but consists mostly of water. To meet its daily energy needs, a vampire bat must take in a huge volume of blood relative to its body size, and it has to be able to fly back to its roost. To maximize protein intake and still be able to fly, the bat gets rid of water fast. The warm fluid flowing down the victim's leg is not blood!

Back in the roost, the bat's challenge is reversed. To digest a high-protein meal, the bat must excrete a lot of nitrogenous waste with minimal loss of water, as it may not get more water until its next meal. So within a few hours, the bat's excretory system has to switch from rapidly excreting water to conserving water, in spite of the need to excrete nitrogenous wastes in the urine. The vampire bat's excretory system rapidly switches from producing lots of dilute urine to producing small amounts of very concentrated urine.

QA How does the excretory system of vampire bats process their high-protein liquid diet?

51.1 Excretory Systems Regulate Osmotic and Ionic Concentrations

Homeostasis of the extracellular fluid (the blood plasma and interstitial fluid; see [Key Concept 39.2](#)) is critical for several reasons:

The solute concentration of the extracellular fluid determines the water balance of the cells of the body.

The specific ionic composition of the extracellular fluid influences many cell functions.

The health of cells requires the elimination of nitrogenous wastes.

The problems that have to be solved to maintain homeostasis of the extracellular fluid depend on the environment in which a species lives (salt water, fresh water, or terrestrial) and its lifestyle, as you saw in the case of the vampire bat in the opening story. Animals depend on [excretory systems](#) to maintain the volume, concentration, and composition of their extracellular fluids, and to excrete wastes.

excretory systems In animals, organs that maintain the volume, solute concentration, and composition of the extracellular fluid by excreting water, solutes, and nitrogenous wastes in the form of urine.

focus your learning

Animal excretory systems use filtration, secretion, and reabsorption to regulate osmolarity and ionic composition of the extracellular fluid.

Aquatic animals either conform to the osmolarity of the environment or expend energy to maintain a constant internal osmolarity.

Osmosis causes water to enter or to leave cells

The volume of a cell depends on whether it takes up water from or loses water to the extracellular fluid. The movement of water across cell membranes via osmosis depends on differences in solute concentration on the two sides of the membrane and on the permeability of the membrane (see [Key Concept 6.3](#)). If the solute concentration of the extracellular fluid is less than that of the cytoplasm, water moves into the cells, causing them to swell and possibly burst (see [Figure 6.10](#)). If the solute concentration of the extracellular fluid is greater than that of the cytoplasm, the cells lose water and shrink. Thus the solute concentration of the extracellular fluid affects both the volume and the solute concentration of the cells.

Animal physiologists use the term [osmolarity](#) in discussing osmosis. The osmolarity of a solution is the number of ***moles** of osmotically active solutes per liter of solvent. Thus a 1-molar solution of glucose is also a 1-osmolar (1 osmole per liter) solution, but a 1-molar solution of sodium chloride (NaCl) is a 2-osmolar solution, because each NaCl molecule dissociates into two osmotically active ions.

osmolarity The concentration of osmotically active particles in a solution.

Excretory systems control extracellular fluid osmolarity and composition

Excretory systems control the osmolarity and composition of the extracellular fluids by excreting solutes that are present in excess (such as NaCl when we eat lots of salty food) and conserving solutes that are valuable or in short supply (such as glucose and amino acids). Excretory systems also eliminate the toxic waste products of protein metabolism. The output of the excretory system is [urine](#).

urine (you' rin) In vertebrates, the fluid waste product containing the toxic nitrogenous by-products of protein and nucleic acid metabolism.

Three basic processes are common to a wide variety of animal excretory systems: filtration, secretion, and reabsorption. Filtered extracellular fluid contains no cells or large molecules, such as proteins. In animals with a closed circulatory system, the blood plasma is filtered from capillaries into associated tubules. The walls of the capillaries and of the tubules are the filter, and the filtration is driven by blood pressure. As the filtrate flows through the tubules, its composition and concentration are modified through processes of secretion and reabsorption to form the urine that leaves the body.

In all of the discussions that follow about the movement of water across membranes, *it is important to remember that there are no mechanisms for the active transport of water*. The movement of water is due either to a pressure difference (filtration) or to a difference in solute concentration (osmosis). Water molecules move down a pressure gradient or up a solute concentration gradient.

Aquatic invertebrates are either ionic conformers or regulators

Most invertebrates that live in seawater conform to the osmotic concentration of their environment over a fairly wide range of salinities and are therefore called [osmoconformers](#) ([Figure 51.1](#)). The osmolarity of seawater in the open ocean is about 1,000 millios-moles/liter (mosm/L), but it can vary quite a bit in estuaries where it is diluted by an influx of fresh water or in evaporating tide pools as the salt gets concentrated. Osmoconformity can result in considerable energetic savings, as it costs metabolic energy to move ions across membranes to achieve osmotic regulation.

osmoconformer An aquatic animal that equilibrates the osmolarity of its extracellular fluid to be the same as that of the external environment. (Contrast with osmoregulator.)

Figure 51.1 Some Marine Invertebrates Osmoregulate Some aquatic animals, such as mussels, experience an extreme range of salt concentrations in their environment and are osmoconformers over much of that range. Other aquatic animals, such as brine shrimp, are osmoregulators in that they maintain a relatively constant osmolarity of their extracellular fluids as environmental salinity varies.

Osmoconformity is not an option for freshwater animals. No cell can do without ions or nutrients, so freshwater animals always have to expend energy to conserve salts and excrete water.

Some marine invertebrates maintain a rather constant osmolarity of their extracellular fluids as the osmolarity of the environment changes, and these animals are therefore called **osmoregulators** (see [Figure 51.1](#)). Osmoregulators in the marine environment mostly maintain their osmotic concentration considerably below that of the environment and are therefore engaged in **hypotonic regulation**. Occasionally, however, seawater is diluted by an influx of fresh water, as in estuaries, and animals must maintain their osmotic concentrations above that of the environment—a process called **hypertonic regulation**.

osmoregulator An aquatic animal that actively regulates the osmolarity of its extracellular fluid. (Contrast with osmoconformer.)

hypotonic regulation Maintaining body fluids at a lesser solute concentration than the environment. (Contrast with hypertonic regulation.)

hypertonic regulation Maintaining body fluids at a greater solute concentration than the environment. (Contrast with hypotonic regulation.)

The brine shrimp *Artemia* illustrated in [Figure 51.1](#) is an osmo-regulator with an enormous range of tolerances. *Artemia* are found in huge numbers in extremely salty environments, such as Utah's Great Salt Lake and in coastal evaporation ponds where salt is concentrated for commercial purposes (see [Figure 25.17](#)) and can reach an osmolarity of 2,500 mosm/L. No animal could survive with internal osmolarities that high; such a solute concentration would cause proteins to denature. *Artemia* are able to exploit these environments because of their ability to regulate hypotonically by actively transporting NaCl from their extracellular fluid out across their gill membranes to the environment. *Artemia* cannot survive in fresh water, but they can live in dilute seawater by reversing the direction of transport of NaCl across their gill membranes to maintain the osmolarity of their extracellular fluids above that of the environment, thus becoming hypertonic regulators.

Invertebrates that are osmoconformers still have to be ionic regulators with respect to certain ions. Although the concentrations of Na^+ and Cl^- in their extracellular fluids may be the same as in seawater, many other ions are regulated at different levels. For example, the concentration of K^+ is usually higher, and the concentrations of Mg^{2+} and of SO_4^{2-} are usually lower, in the extracellular fluids than in the seawater. Active transporters maintain the regulated ions in the extracellular fluid at optimal concentrations.

Vertebrates are osmoregulators and ionic regulators

All aquatic vertebrates, with two exceptions, regulate the osmolarity of their extracellular fluids at around 300 mosm/L. In doing so, they are selective in which ions they conserve and which ions they excrete; thus they are ionic regulators and osmoregulators. One exception is the hagfish, a primitive jawless fish and a very ancient vertebrate group (see [Figure 32.11](#)). Hagfishes are osmoconformers as well as ionic conformers for most of the ions found in seawater. The other exception is members of the class Chondrichthyes (cartilaginous fishes, the sharks and rays). The cartilaginous fishes retain in their extracellular fluid two organic solutes, urea and trimethylamine oxide (TMAO), that are products of protein metabolism. As a result, their extracellular fluid is slightly hypertonic to the seawater and they gain water by osmosis.

Terrestrial vertebrates obtain their salts mostly from food, and they regulate the ionic composition of their extracellular fluids by conserving some ions and excreting others. For example, herbivores have to conserve Na^+ because most plants have low concentrations of Na^+ . In contrast, birds that feed on marine animals must excrete the excess sodium they ingest with their food. Such birds, which include penguins and gulls, excrete excess salt through nasal salt glands. These glands use secondary active transport of Cl^- ions (with Na^+ and some water following passively) into a series of canals and ducts to produce a concentrated solution of NaCl that empties into the nasal cavity ([Figure 51.2](#)). These birds can be seen frequently sneezing or shaking their heads to get rid of the salty droplets excreted from their nasal salt glands.

Figure 51.2 Nasal Salt Glands Excrete Excess Salt (A) Marine birds have nasal salt glands that excrete the excess salt they ingest with their food. **(B)** This giant petrel has returned from a feeding trip at sea and is secreting salt through its nasal salt gland.

51.1 recap

Excretory systems control water and salt balance and the excretion of nitrogenous waste products through three mechanisms: filtration of body fluids to form urine, active secretion of substances into the urine, and active reabsorption of substances from the urine.

learning outcomes

You should be able to:

- Describe the roles of filtration, secretion, and reabsorption in the excretory systems of animals with closed circulatory systems.
- Given data about the extracellular composition and environment of a particular species, determine its osmoregulatory characteristics.

1. What is the significance of a closed circulatory system for osmoregulation in a freshwater vertebrate?
2. Why is it important for an animal like *Artemia* that lives in the intertidal zone to be able to osmoregulate, and how does *Artemia* do that at the extremes of salinities in its environment?
3. How does water get into the nasal salt gland ducts of marine birds?

In addition to maintaining salt and water balance, animals must eliminate the waste products of metabolism from their extracellular fluids. The major problem is nitrogen. When nitrogen-containing molecules are broken down by metabolism, the end product can be toxic.

***connect the concepts** As described in [Key Concept 2.4](#), a mole is the amount of a substance in grams that is numerically equal to its molecular weight.

51.2 Animals Excrete Nitrogen as Ammonia, Urea, or Uric Acid

The end products of the metabolism of carbohydrates and fats are water and carbon dioxide, which are not difficult to eliminate. Proteins and nucleic acids, however, contain nitrogen, so their metabolism produces nitrogenous wastes in addition to water and carbon dioxide.

focus your learning

Nitrogenous waste products have different advantages in different environments.

Excreting uric acid conserves water.

Ammonia is toxic

The most common nitrogenous waste is **ammonia** (NH_3). Because it is highly toxic, ammonia is either excreted continuously to prevent its accumulation or is detoxified by conversion into **urea** or **uric acid** (Figure 51.3). Ammonia is highly soluble in water and diffuses rapidly, so its continuous excretion is relatively simple for many aquatic animals that continuously lose ammonia from their blood to the environment by diffusion across their gill membranes. Animals that excrete ammonia, such as aquatic invertebrates and bony fishes, are called **ammonotelic**.

ammonia NH_3 , the most common nitrogenous waste. (Compare with urea, uric acid.)

urea (you ree' uh) A compound that is the main form of nitrogen excreted by many animals, including mammals. (Compare with ammonia, uric acid.)

uric acid A compound that serves as the main excreted form of nitrogen in some animals, particularly those which must conserve water, such as birds, insects, and reptiles. (Compare with ammonia, urea.)

ammonotelic (am moan' o teal' ic) [Gk. *telos*: end] Pertaining to an organism in which the final product of breakdown of nitrogen-containing compounds (primarily proteins) is ammonia. (Contrast with ureotelic, uricotelic.)

Figure 51.3 Nitrogenous Waste Products of Metabolism The metabolism of proteins and nucleic acids produces nitrogenous wastes. Many aquatic animals, including most fishes, excrete nitrogenous wastes as ammonia, which is highly diffusible and soluble in an aqueous environment. Most terrestrial animals and some aquatic animals excrete either urea or uric acid. Urea is more soluble in water and is the major nitrogenous excretory product for mammals, amphibians, and some fishes. Uric acid is not very soluble in water and is the major nitrogenous excretory product for reptiles (including birds), insects, and some amphibians.

Ammonia can also be lost by diffusion across the alveolar membranes of air-breathing animals, but with tidal ventilation, the buildup of ammonia in the extracellular fluids would be greater and therefore toxic. Therefore these animals detoxify ammonia by converting it into urea or uric acid.

Urea is highly soluble in water

Mammals, amphibians, cartilaginous fishes (sharks and rays), and hagfishes excrete urea as their principal nitrogenous waste product and are therefore called **ureotelic**. Urea is quite soluble in water, but its excretion can result in a large loss of water that many animals can ill afford. Mammals have somewhat solved this problem through the evolution of excretory systems that can produce urine with a high concentration of urea, thereby decreasing the water loss associated with excretion of urea. Also, recall from [Key Concept 51.1](#) that sharks and rays solve the water loss problem of living in sea water by retaining high concentrations of urea and TMAO in their extracellular fluid, so that it is hyperosmotic to seawater.

ureotelic Pertaining to an organism in which the final product of the breakdown of nitrogen-containing compounds (primarily proteins) is urea. (Contrast with ammonotelic, uricotelic.)

Uric acid is not very soluble in water

A single molecule of uric acid eliminates twice the amount of nitrogen as does a molecule of urea (see [Figure 51.3](#)), but uric acid is not very soluble in water. Therefore it tends to precipitate out of solution and form a colloidal suspension in the urine and is excreted as a semisolid (for example, the whitish material in bird droppings). Because of the precipitation of the uric acid out of solution in the excretory system, water can be reabsorbed from the urine and thereby reduce

the water loss necessary to excrete the nitrogenous waste. Animals that excrete uric acid are **uricotelic**, and they include insects, reptiles (including birds), and some amphibians. Many uricotelic species live in very arid environments.

uricotelic Pertaining to an organism in which the final product of the breakdown of nitrogen-containing compounds (primarily proteins) is uric acid. (Contrast with ammonotelic, ureotelic.)

Most species produce more than one nitrogenous waste

Humans are ureotelic, but we also excrete uric acid. The uric acid in human urine comes largely from the metabolism of nucleic acids. If uric acid levels in the extracellular fluid rise too high, uric acid can precipitate in joints, causing the age-old malady gout. Because solubility goes down with temperature, uric acid usually precipitates first in the extremities, especially the big toe. Pain in the big toe is a telltale symptom of gout. The risk for developing gout goes up with excessive consumption of protein, beer, and spirits (less so with wine) and in general with obesity and insulin resistance. Therefore in the past it was called “the disease of rich men.” Gout has been around for a very long time; the first documented case was in Egypt around 2500 B.C.E.

Humans can also excrete ammonia, which is an important mechanism for regulating the pH of the extracellular fluids. As you will see later in this chapter, excreted ammonia buffers the urine and enables the excretion of excess hydrogen ions.

Species that live in different habitats at different developmental stages may use more than one mechanism of nitrogen excretion. The tadpoles of frogs and toads, for example, excrete ammonia across their gill membranes, but adult frogs and toads generally excrete urea. Some adult amphibians that live in arid habitats excrete uric acid.

51.2 recap

Ammonia is a common metabolic waste product of nitrogen-containing molecules. Most aquatic animals excrete ammonia by diffusion into the water. Terrestrial animals and some aquatic animals detoxify ammonia by converting it to urea or uric acid.

learning outcomes

You should be able to:

- Compare the properties of ammonia, urea, and uric acid as nitrogenous waste products.
- Describe the relative advantages and disadvantages of excreting nitrogenous waste as urea or as uric acid.

1. When amino acids are broken down, a first step is removal of the amine group, forming ammonia. What happens to that ammonia in a fish and in a mammal? Explain why this happens.
2. Why do sharks and rays produce urea rather than uric acid to raise the osmotic concentration of their extracellular fluids?
3. For terrestrial animals, what is the advantage of excreting uric acid as the nitrogenous waste product?

Animals exhibit a variety of adaptations for dealing with the challenges of salt and water balance

in different environments. All of these adaptations, however, are based on two basic mechanisms—namely, filtration and tubular processing of the filtrate to conserve some solutes and excrete others.

51.3 Invertebrate Excretory Systems Use Filtration, Secretion, and Reabsorption

Freshwater and terrestrial invertebrates have a wide variety of adaptations for maintaining salt and water balance and excreting nitrogen. Here we explore three examples of invertebrate excretory systems: protonephridia, metanephridia, and Malpighian tubules. Each of these systems produces an extract of interstitial fluid lacking large molecules. They then change the solute composition (ions and small molecules) of that fluid to form an excretory product.

focus your learning

Vertebrates have evolved to occupy fresh and salt water and dry terrestrial habitats.

Metanephridia of annelids filter blood from their closed circulatory systems and process the resulting filtrate by secretion and reabsorption in a system of tubules.

Malpighian tubules use active transport of solutes, including uric acid, to pull extracellular fluid into the tubules osmotically; precipitation of the uric acid enables reabsorption of water.

Protonephridia of flatworms excrete water and conserve salts

Many free-living flatworms, such as *Planaria*, live in fresh water. These animals excrete water through an elaborate network of tubules running throughout their bodies. The tubules end in flame cells, so called because each cell has a tuft of cilia projecting into the tubule ([Figure 51.4](#)). The beating of the cilia gives the appearance of a flickering flame. A flame cell and a tubule together form a [protonephridium](#) (plural *protonephridia*; Greek *proto*, “before,” + *nephros*, “kidney”).

Figure 51.4 Protonephridia in Flatworms The protonephridia of the freshwater flatworm *Planaria* consist of tubules ending in flame cells. In the region of the flame cells, body fluid is filtered between the tubule cells. The composition of the filtrate is modified as it flows down the tubule. Black arrows indicate direction of flow of tubular fluid.

Q: Do you expect the fluid coming out of the excretory pore to be hypertonic or hypotonic to the flatworm's interstitial fluid?

protonephridium (plural: protonephridia) [Gk. *proto*: before + *nephros*: kidney] The excretory organ of flatworms, made up of a tubule and a flame cell.

Extracellular fluid enters the tubules by filtration. The beating of the cilia causes a slight negative pressure in the tubule, and movements of the animal create positive pressure in the extracellular fluid. This pressure difference causes extracellular fluid to be filtered through tiny spaces between tubule cells. The filtrate flows toward the animal's excretory pore, and along the way the cells of the tubules modify the composition of the fluid by reabsorption and secretion of specific ions and molecules. Because more ions are reabsorbed than are secreted, the urine that leaves the flatworm's body is less concentrated than the extracellular fluid. Thus the protonephridium conserves ions and excretes water and wastes.

Metanephridia of annelids process coelomic fluid

Filtration of body fluids and modification of urine by tubules are highly developed processes in annelids such as the earthworm. Annelids are segmented, and in each segment they have a fluid-filled body cavity called a coelom (see [Figure 31.11](#)). Annelids have a closed circulatory

system through which blood is pumped under pressure. The pressure causes the blood to be filtered across the thin, permeable capillary walls into the coelom. Some waste products, such as ammonia, diffuse directly from the tissues into the coelom. Where does this coelomic fluid go?

Each segment of the earthworm contains a pair of **metanephridia** (singular *metanephridium*; Greek *meta*, “akin to”). Each metanephridium begins as a ciliated, funnel-like opening called a nephrostome. The nephrostome resides in one segment and continues as a tubule in the next segment. The tubule ends in a pore, called a nephridiopore, that opens to the outside of the animal (**Figure 51.5**). Coelomic fluid is swept into the metanephridia through the ciliated nephrostomes. As the fluid passes through the tubules, their cells actively reabsorb certain molecules from it and actively secrete other molecules into it. What leaves the animal through the nephridiopores is a dilute urine containing nitrogenous wastes and other solutes.

metanephridia (singular: metanephridium) [Gk. *meta*: akin to) The paired excretory organs of annelids.

Figure 51.5 Metanephridia in Earthworms The metanephridia of annelids are arranged segmentally. The cross section at the left end shows a pair of metanephridia. Three longitudinal sections (right) show only one metanephridium of the two in each segment. Coelomic fluid enters the nephrostome and flows through tubules leading to the nephridiopore. A close association of the tubules and blood capillaries facilitates the active exchange of substances between the blood and the tubular fluid.

Malpighian tubules of insects use active transport to excrete wastes

Insects can excrete nitrogenous wastes with very little loss of water and can therefore live in the driest habitats on Earth. The insect excretory system consists of **Malpighian tubules**. An individual insect has from 2 to more than 100 of these blind-ended tubules that open into the gut between the midgut and hindgut (**Figure 51.6**).

Malpighian tubule (mal pee' gy un) A type of protonephridium found in insects.

Figure 51.6 Malpighian Tubules in Insects The blind, thin-walled Malpighian tubules are attached to the junction of the insect's midgut and hindgut and project into the spaces containing extracellular fluid. This system makes it possible to excrete wastes with very little loss of water.

Q: Why are Na^+ and K^+ ions transported into the Malpighian tubule but then transported out of the hindgut and rectum?

Insects have an open circulatory system and therefore cannot use a pressure difference to filter extracellular fluids into the Malpighian tubules. Instead, the cells of the tubules actively transport uric acid, potassium ions, and sodium ions from the extracellular fluid into the tubules. The high concentration of solutes in the tubules causes water to follow osmotically, which flushes the tubule contents toward the gut.

The epithelial cells of the hindgut and rectum actively transport sodium and potassium ions from the gut contents back into the extracellular fluid. This local transport of salts creates an osmotic gradient that pulls water out of the rectal contents. As its concentration increases, the uric acid forms a colloidal suspension, freeing even more water to be reabsorbed. Remaining in the rectum is the uric acid mixed with other wastes; this semisolid matter is what the insect excretes. If you ever park your car under a tree being visited by bees, you will find the little excretory droplets from the bees all over the car. The Malpighian tubule system is a highly effective mechanism for excreting nitrogenous wastes and some salts without giving up much water.

Protonephridia and metanephridia work by creating a filtrate of the body fluids that is modified by the secretion and reabsorption of specific substances before being excreted. Insect Malpighian tubules actively secrete uric acid and other solutes into closed tubules.

learning outcomes

You should be able to:

- Describe the structure and function of a protonephridium.
 - Diagram the process of urine formation by a metanephridium.
 - Explain how Malpighian tubules enable insects to live in very arid habitats.
-

1. How do protonephridia enable flatworms to live in fresh water?
 2. What are the relationships among blood plasma, coelo-mic fluid, and urine in an annelid worm?
 3. How does the insect excretory system conserve water?
-

Having described how several invertebrate groups handle nitrogen excretion, we will next consider the nephron—the basic unit of the vertebrate excretory system—and how it evolved to be able to respond to a variety of salt- and water-balance challenges and maintain a relatively constant internal environment.

51.4 The Nephron Is the Basic Functional Unit of Vertebrate Excretory Systems

The main excretory organ of vertebrates is the [kidney](#), and the functional unit of the kidney is the [nephron](#), which has a blood vessel component and a tubule component. The vascular component begins with a knot of capillaries that are highly permeable and filter the blood into the tubule component. Processes of secretion and reabsorption in the tubules produce urine, which differs in composition from the extracellular fluids of the body.

kidneys A pair of excretory organs in vertebrates.

nephron (nef' ron) [Gk. *nephros*: kidney] The functional unit of the kidney, consisting of a structure for receiving a filtrate of blood and a tubule that reabsorbs selected parts of the filtrate.

focus your learning

Reptiles can be more independent of water sources than amphibians can.

The nephron produces urine through filtration of blood plasma in the glomerulus and tubular processing of the filtrate by reabsorption and secretion of solutes.

Glomerular filtration involves anatomical features of glomerular capillaries and cells of Bowman's capsule.

The liquid that enters Bowman's capsule is called the renal filtrate and is further processed into urine as it moves through the renal tubules of the nephron.

The evolution of vertebrates is thought to have begun with a marine ancestor that moved into a freshwater habitat. The excretory system of this vertebrate ancestor would have evolved to excrete large quantities of water while conserving salts. But if the early vertebrate excretory system evolved in response to the need to excrete water, how did subsequent vertebrate lineages adapt to environments where water must be conserved and salts excreted? The answer to this question differs among vertebrate groups. Even among marine fishes, the excretory adaptations of the bony fishes differ from those of the cartilaginous fishes. Reptiles, including birds, and mammals have excretory systems that conserve water. The reptiles achieve this mainly by being uricotelic and producing a semisolid excretory product that contains little water. Mammals, in contrast, are ureo-telic; they excrete a liquid waste product but have evolved the ability to produce highly concentrated urine.

Marine fishes must conserve water

Marine bony fishes osmoregulate their extracellular fluids to maintain them at one-third to one-half the osmolarity of seawater. Thus marine bony fishes must conserve water, which they are constantly losing through osmosis, and must excrete excess solutes. Marine bony fishes cannot produce urine that is more concentrated than their extracellular fluids, so they minimize water loss by producing very little urine. In contrast, freshwater fishes produce lots of dilute urine.

How do marine bony fishes deal with the large salt loads they ingest with food? Marine bony

fishes do not absorb from their gut some of the ions they take in, especially divalent ions such as Mg^{2+} and SO_4^{2-} . NaCl, the major salt ingested, is actively excreted across the gill membranes. As mentioned earlier, bony fishes can lose their nitrogenous waste, ammonia, by diffusion across their gill membranes.

Sharks and rays are osmoconformers but not ionic conformers. As mentioned earlier, they raise the osmolarity of their body fluids by retaining urea and TMAO making their extracellular fluids hyperosmotic to seawater. These species have adapted to a concentration of urea in the body fluids that would be toxic to other vertebrates. Sharks and rays still have the problem of excreting the large amount of salts they take in with their food. They solve this problem by having a gland in the rectum that actively secretes NaCl by a mechanism similar to that of the nasal salt glands of seabirds.

Terrestrial amphibians and reptiles must avoid desiccation

Most amphibians live in or near fresh water, and they usually stay in humid habitats when they do venture from the water. Like freshwater fishes, most amphibians produce large amounts of dilute urine and conserve salts. Some amphibians, however, have adapted to habitats that require water conservation.

Amphibians living in dry terrestrial environments have skin with a reduced permeability to water. Some secrete a waxy substance over the skin for waterproofing. Several species of frogs that live in arid regions of Australia burrow into the ground and remain there during long dry periods. They enter [estivation](#), a state of very low metabolic activity and therefore low water turnover. When it rains, the frogs come out of estivation, feed, and reproduce. Their most interesting adaptation is an enormous urinary bladder. Before entering estivation, they fill the bladder with dilute urine, which can amount to one-third of their body weight. This dilute urine serves as a water reservoir that is gradually reabsorbed into the blood during the long period of estivation. Aboriginal peoples have learned to locate these buried frogs and use them as an emergency source of water.

estivation (ess tuh vay' shun) [L. *aestivalis*: summer] A state of dormancy and hypometabolism that occurs during the summer; usually a means of surviving drought and/or intense heat. (Contrast with hibernation.)

Reptiles occupy habitats ranging from aquatic to extremely hot and dry. In fact, snakes, lizards, and birds are among the most prominent members of many desert faunas. Three major adaptations have freed reptiles from the close association with water that is necessary for most amphibians (see [Key Concept 33.4](#)):

- . Reptiles are amniotes that do not need fresh water to reproduce because they employ internal fertilization and lay eggs with shells that retard evaporative water loss.
- . Reptiles have a dry epidermis (skin) that retards evaporative water loss.
- . Reptiles excrete nitrogenous wastes as uric acid semisolids, losing little water in the process.

Mammals can produce highly concentrated urine

Mammals occupy diverse habitats, many of which present special excretory system challenges. The most challenging environments are those in which water is severely limited. Mammals have a variety of adaptations to conserve water, but chief among them is the ability to produce urine that is more concentrated than their extracellular fluids. They are able to concentrate their urine because of adaptations of their kidneys that we will explore in detail in [Key Concept 51.5](#). To understand how these adaptations work, you must first know the structure and function of the

vertebrate nephron.

The nephron is the functional unit of the vertebrate kidney

Urine formation in vertebrate nephrons involves three main processes ([Figure 51.7](#)):

Figure 51.7 The Vertebrate Nephron The vertebrate nephron consists of a renal tubule closely associated with two capillary beds, the glomerulus and the peritubular capillaries.

Activity 51.2 The Vertebrate Nephron www.Life11e.com/ac51.2

Filtration. Each nephron has a dense bed of capillaries called a **glomerulus** (plural *glomeruli*). The glomerulus is highly permeable to water, ions, and small molecules but impermeable to large molecules. Blood pressure drives the movement of water and small-molecular-weight solutes out of the glomerular capillaries.

Tubular reabsorption. The filtrate from the glomerulus flows into the [renal tubule](#). Cells in the renal tubule modify the filtrate by reabsorbing specific ions, nutrients, and water, returning these to the blood, and leaving behind and concentrating excess ions and waste products such as urea.

Tubular secretion. The filtrate in the renal tubule is further modified by tubule cells transporting substances into the tubule. These are substances that the body needs to excrete.

glomerulus (glo mare' yew lus) (plural: glomeruli) [L. *glomus*: ball] Sites in the kidney where blood filtration takes place. Each glomerulus consists of a knot of capillaries served by afferent and efferent arterioles.

renal tubule A structural unit of the kidney that collects filtrate from the blood, reabsorbs specific ions, nutrients, and water and returns them to the blood, and concentrates excess ions and waste products such as urea for excretion from the body.

Blood enters the glomerular capillaries via an [afferent arteriole](#) and leaves the glomerulus in an [efferent arteriole](#). This short vessel is called an arteriole because it feeds another capillary bed, called the [peritubular capillaries](#). These capillaries intimately surround the renal tubules and deliver substances to the renal tubules that the cells of the tubules secrete into the urine. The peritubular capillaries also carry away substances that the tubule cells reabsorb from the urine.

afferent (af' ur unt) [L. *ad*: toward + *ferre*: to carry] Carrying to, as in neurons that carry impulses to the central nervous system (**afferent neurons**), or a blood vessel that carries blood to a structure (**afferent arterioles**). (Contrast with efferent.)

efferent (ef' ur unt) [L. *ex*: out + *ferre*: to bear] Carrying outward or away from, as in neurons that carry impulses outward from the central to the peripheral nervous system (**efferent neurons**), or a blood vessel that carries blood away from a structure (**efferent arterioles**). (Contrast with afferent.)

peritubular capillaries Small blood vessels that surround the renal tubules.

Blood is filtered into Bowman's capsule

The renal tubule begins with [Bowman's capsule](#) (see [Figure 51.7](#)), which encloses the glomerulus ([Figure 51.8A and B](#)). The glomerulus appears to be pushed into Bowman's capsule much like a fist pushed into an inflated balloon. The cells of the capsule that are in direct contact with the glomerular capillaries are called [podocytes](#) ([Figure 51.8C](#)). These highly specialized cells have numerous extensions, each with hundreds of fine processes. The podocytes wrap around the capillaries so that their processes interdigitate and intimately cover the capillaries.

Bowman's capsule An elaboration of the renal tubule, composed of podocytes, that surrounds and collects the filtrate from the glomerulus.

podocytes Cells of Bowman's capsule of the nephron that cover the capillaries of the glomerulus, forming filtration slits.

Figure 51.8 Tour of the Nephron Scanning electron micrographs illustrate the anatomical basis for blood filtration in the kidneys. **(A)** This cross section of an intact glomerulus shows the tubule cells that form Bowman's capsule surrounding the glomerular capillaries. **(B)** In a preparation showing only the blood vessels (tubular tissue has been digested away), the glomeruli appear as balls of capillaries served by arterioles. **(C)** Higher magnification of a glomerulus with the tubule cells intact shows the podocytes that wrap around the glomerular capillaries. **(D)** The glomerular filter has three layers: the fenestrated endothelial cells of the capillaries, the meshwork of collagen fibers making up the basement membrane, and the filtration slits between the podocyte processes. All three layers have negative charges, which contribute to their ability to prevent the passage of protein molecules.

The glomerulus filters the blood, producing a fluid (the renal filtrate) that lacks cells and large molecules. The walls of the capillaries, the basal lamina of the capillary endothelium, and the podocytes of Bowman's capsule all participate in filtration. Fenestrations in the walls of the capillaries (see [Key Concept 49.4](#)) allow water and many solute molecules, but not red blood cells, to pass through. The meshwork of the basal lamina and the spaces between the processes of the podocytes are even finer and prevent large molecules from leaving the capillaries ([Figure 51.8D](#)). The arterial pressure of the blood entering the permeable capillaries causes the filtration of water and small molecules out of the glomerular capillaries and into the Bowman's capsule. The glomerular filtration rate is high because blood pressure in the glomerular capillaries is high, and because the capillaries of the glomerulus, along with their covering of podocytes, are more permeable to water than are other capillary beds in the body.

You will recall that marine bony fishes produce very little urine. The explanation for this is that their kidneys have evolved to have few if any glomeruli, whereas the kidneys of freshwater fishes have many glomeruli.

The renal tubules convert glomerular filtrate to urine

The composition of the filtrate that enters the renal tubule is similar to that of the blood plasma, except the filtrate lacks high-molecular-weight solutes such as proteins. Reabsorption and secretion cause the composition of this fluid to change as it passes down the renal tubule. Cells of the tubule actively reabsorb certain molecules from the tubule fluid (which are returned to the

blood flowing through the peritubular capillaries). For example, glucose and amino acids are reabsorbed. Most NaCl is reabsorbed. Other substances in the blood of the peritubular capillaries are actively secreted into the tubule fluid. An example is para-aminohippuric acid (PAH), which is produced in the liver from benzoic acid, a common food preservative. Because of the actions of the renal tubules, the excreted urine is very different from the original glomerular filtrate.

51.4 recap

The kidney is the major excretory organ of vertebrates. Its functional unit is the nephron, which includes a glomerulus that filters blood and a renal tubule that secretes and reabsorbs solutes, modifying the filtrate to produce urine. As seen in freshwater fishes, the nephron evolved as a mechanism for excreting excess water while conserving valuable solutes. Vertebrates have various adaptations for conserving water. Marine bony fishes produce very little urine but lose nitrogenous waste as ammonia across their gills and also excrete salts across their gills. Marine cartilaginous fishes produce urea and retain it, so their extracellular fluids are hyperosmotic to the environment and therefore take up water by osmosis. Many terrestrial vertebrates conserve water by excreting nitrogenous waste as uric acid, by minimizing evaporative water loss, and by active secretion of salts. Mammals have the ability to conserve water by producing urine that is more concentrated than their extracellular fluid.

learning outcomes

You should be able to:

- Relate structural and behavioral features of amphibians and reptiles to their abilities to minimize water loss.
- Describe the organization of blood vessels in the nephron.
- Explain the mechanism of filtration of blood plasma from the glomerular capillaries into Bowman's capsule.
- Explain why the renal filtrate changes in composition as it passes through the nephron.

-
1. What is the connection between the need to conserve water and the evolution of internal fertilization?
 2. What are the roles of the afferent and efferent arterioles in the nephron?
 3. What are the anatomical components of the filtration mechanism in the glomerulus?
 4. How does the composition of the urine become different from the composition of the blood?

The adaptations that enable the mammalian kidney to produce urine more concentrated than extracellular fluids were important steps in vertebrate evolution, and they were largely achieved through changes in the structure and regional functions of the renal tubules. These changes converted a kidney that evolved to excrete water into an organ that conserves water.

51.5 The Mammalian Kidney Can Produce Concentrated Urine

Mammals have high body temperatures and high metabolic rates, and therefore have the potential for a high rate of water loss and a high level of nitrogenous waste production. Having an excretory system that minimizes water loss made it possible for these highly active species to occupy arid habitats.

focus your learning

Nephrons are organized in the kidney so that the glomeruli and major portions of the renal tubules (called convoluted tubules) are in the outer region, or cortex, and straight sections of tubules (called loops of Henle) and collecting ducts are in the inner region, or medulla.

Most of the filtrate is reabsorbed isosmotically in the proximal convoluted tubule.

Loops of Henle are countercurrent multipliers that create a concentration gradient in the extracellular fluid.

As the tubular fluid passes down the collecting duct, water can be reabsorbed into the extracellular fluid to produce a more concentrated urine in the tubule.

The mammalian kidney functions in conjunction with the lungs to regulate the pH of the extracellular fluid.

 Media Clip 51.1 Inside the Bladder www.Life11e.com/mc51.1

Kidneys produce urine and the bladder stores it

Mammalian excretory systems are similar, so we will use that of humans as our example. Humans have two kidneys at the back of the upper region of the abdominal cavity ([Figure 51.9A](#)). Each kidney filters blood, processes the filtrate into urine, and releases that urine into a duct called the [ureter](#). The ureter of each kidney leads to the [urinary bladder](#), where the urine is stored until it is excreted through the [urethra](#), a short tube that opens to the outside of the body.

Figure 51.9 The Human Excretory System (A) The kidneys lie against the back wall of the abdominal cavity, in the region of the middle back. The adrenal glands (see [Figure 40.16](#)) are positioned on top of the kidneys; they are the source of the hormone aldosterone, which plays a role in the regulation of kidney function. (B) A highly organized internal structure is the basis for kidney function. Certain parts of the nephrons are in the organ's outer region, the cortex; other parts are in the internal region, the medulla. (C) The glomeruli and the proximal and distal convoluted tubules are located in the cortex of the kidney. The loops of Henle run in parallel as straight sections down into the renal medulla and back up to the cortex. Collecting ducts run from the cortex to the inner surface of the medulla, where they open into the ureter. The vasa recta are peritubular capillaries that parallel the loops of Henle and are permeable to salts and water.

Q: How do you think the osmolarity of the blood in the vasa recta compares with the osmolarity of the interstitial fluid at different levels of the medulla?

Activity 51.3 The Human Excretory System www.Life11e.com/ac51.3

ureter (your' uh tur) Long duct leading from the vertebrate kidney to the urinary bladder or the cloaca.

urinary bladder A structure in which urine is stored until it can be excreted to the outside of the body.

urethra (you ree' thra) In most mammals, the canal through which urine is discharged from the bladder and which serves as the genital duct in males.

Two sphincter muscles surrounding the base of the urethra control urination. One of these sphincters is a smooth muscle and is controlled by the autonomic nervous system. As the bladder fills, stretch receptors in the walls of the bladder trigger a spinal reflex that relaxes this sphincter. This reflex is the only control of urination in infants, hence their frequent "accidents." The other sphincter is a skeletal muscle and is controlled by the voluntary nervous system. When the bladder is very full, only deliberate conscious effort prevents urination. Toilet training

of children teaches them to control this sphincter.

Nephrons have a regular arrangement in the kidney

The kidney is shaped like a kidney bean. When sliced along its long axis on the midline, its key anatomical features are revealed ([Figure 51.9B](#)). The ureter and the [renal artery](#) and [renal vein](#) enter the kidney on its concave (punched-in) side. Inside the kidney, the ureter is continuous with structures that envelop kidney tissues called [renal pyramids](#). The renal pyramids make up the internal core, or [medulla](#), of the kidney. The medulla is covered by an outer layer, or [cortex](#), that has a granular appearance. Between the cortex and the medulla, the renal artery divides into the many arterioles that serve the nephrons. In this same region, the renal vein collects blood from the many venules that drain the peritubular capillaries.

renal artery The main artery supplying the kidney.

renal vein The main vein carrying blood from the kidney.

renal pyramids Tissue of the renal medulla that projects into and releases urine into the renal pelvis which is drained by the ureter.

medulla (meh dull' luh) (1) The inner, core region of an organ, as in the adrenal medulla (adrenal gland) or the renal medulla (kidneys). (2) The portion of the brainstem that connects to the spinal cord.

cortex [L. *cortex*: covering, rind] (1) In plants, the tissue between the epidermis and the vascular tissue of a stem or root. (2) In animals, the outer tissue of certain organs, such as the adrenal gland (adrenal cortex) and the brain (cerebral cortex).

The organization of nephrons within the kidney is very regular. All of the glomeruli with their Bowman's capsules are located in the cortex. The initial segments of the renal tubules that come from the Bowman's capsules are called the [proximal convoluted tubules](#)—"proximal" because they are closest to the glomerulus, and "convoluted" because they are twisted ([Figure 51.9C](#)). All of the proximal convoluted tubules are located in the cortex.

proximal convoluted tubule The initial segment of a renal tubule, closest to the glomerulus. (Compare with distal convoluted tubule.)

At the point at which the proximal convoluted tubule enters the medulla, it becomes thin, straight, and descends directly down toward the tip of a renal pyramid. In the medulla the tubule makes a hairpin turn and ascends back to the cortex, forming what is called a [loop of Henle](#). Some nephrons have longer loops of Henle than others. Some 20-30 percent of human nephrons that have glomeruli deep in the cortex (i.e., near the border with the medulla) have long loops of Henle that go deep into the medulla. Nephrons that have glomeruli farther up in the cortex generally have short loops of Henle that descend only a short distance into the medulla. As you will see, the long loops are the critical adaptation of the mammalian nephron that enables the kidney to concentrate the urine.

loop of Henle (hen' lee) Long, hairpin loop of the mammalian renal tubule that runs from the cortex down into the medulla and back to the cortex; creates a concentration gradient in the interstitial fluids in the medulla.

The ascending limb of the loop of Henle becomes the **distal convoluted tubule** when it reaches the cortex—"distal" because it is farther from the glomerulus. The distal convoluted tubules of many nephrons join a common **collecting duct** in the cortex. The collecting ducts descend back down through the renal pyramid, parallel to and past the tips of the loops of Henle, and empty into a funnel-shaped structure called the pelvis. Divisions of the pelvis that surround each renal pyramid join together to leave the kidney as the ureter (see [Figure 51.9B](#)).

distal convoluted tubule The portion of a renal tubule from where it reaches the renal cortex, just past the loop of Henle to where it joins a collecting duct. (Compare with proximal convoluted tubule.)

collecting duct In vertebrates, a tubule that receives urine produced in the nephrons of the kidney and delivers that fluid to the ureter for excretion.

The organization of the blood vessels of the kidney closely parallels the organization of the nephrons (see [Figure 51.9C](#)). Smaller arteries branch from the renal artery and radiate into the cortex, forming the afferent arterioles that carry blood to each glomerulus. Each glomerulus is drained by an efferent arteriole that gives rise to the peritubular capillaries, most of which surround the proximal and distal convoluted tubules. The intimate associations of the glomerular and peritubular capillaries with the renal tubules enable exchanges between the blood and the specialized regions of the tubules.

Some of the peritubular capillaries run into the medulla in parallel with the loops of Henle and the collecting ducts, forming a vascular network called the **vasa recta**. All of the peritubular capillaries from a nephron join back together into a venule that joins with venules from other nephrons and eventually leads to the renal vein. As you will see, the concentrating ability of the mammalian kidney depends on water reabsorption in the renal medulla, and the vasa recta are the avenue by which that water gets out of the renal medulla and back into the circulation.

vasa recta Blood vessels that parallel the loops of Henle and the collecting ducts in the renal medulla of the kidney.

Most of the glomerular filtrate is reabsorbed by the proximal convoluted tubule

Most of the water and solutes filtered by the glomerulus are reabsorbed and do not appear in the urine. We can reach this conclusion by comparing the rate of filtration by the glomeruli with the rate of urine production. The kidneys receive about 1 liter of blood per minute, or about 1,500 liters of blood per day. How much of this huge volume is filtered out of the glomeruli? The answer is about 12 percent. This is still a large volume—180 liters per day! We normally urinate less than 2 liters per day, so about 99 percent of the fluid volume that is filtered out of the glomerulus is returned to the blood. Where and how is this enormous amount of fluid reabsorbed?

The proximal convoluted tubule (PCT) is responsible for most of the reabsorption of water and solutes from the glomerular filtrate. The cells of this section of the renal tubule have many microvilli that increase their apical (facing into the tubule) surface area for reabsorption, and they have many mitochondria—an indication that they are metabolically active. PCT cells actively transport Na^+ (with Cl^- following) and other solutes, such as glucose and amino acids, out of the tubule fluid.

Almost all glucose and amino acid molecules that are filtered from the blood are actively reabsorbed by PCT cells and transported into the extracellular fluid. The active transport of solutes from the proximal tubule into the interstitial fluid causes water to follow osmotically. The

water and solutes moved into the interstitial fluid are taken up by the peritubular capillaries and returned to the venous blood. These processes accomplish the reabsorption of more than 75 percent of the fluid that initially enters the nephron.

Despite the bulk reabsorption of water and solutes by the PCT, the overall osmolarity of the fluid flowing through the PCT does not change. Thus the process that is occurring in the PCT is called isosmotic reabsorption. The fluid that enters the loop of Henle has the same osmolarity as the blood plasma, although its composition is different. How then does the kidney produce urine that is more concentrated than the blood plasma?

The loop of Henle creates a concentration gradient in the renal medulla

Humans can produce urine that is four times more concentrated than their blood plasma. The vampire bat you encountered at the beginning of this chapter can produce urine that is 15 times more concentrated than its blood plasma ([Investigating Life: How Can Vampire Bats Use Blood as Fast Food?](#)). The concentrating ability of the mammalian kidney arises from a [countercurrent multiplier](#) mechanism made possible by the anatomical arrangement of the loops of Henle. The term “countercurrent” refers to the opposing directions of fluid flow in the descending and ascending limbs. The term “multiplier” refers to the ability of this system to create a solute concentration gradient in the renal medulla.

How Can Vampire Bats Use Blood as Fast Food?

experiment

Original Paper: Busch, C. 1988. Consumption of blood, renal function and utilization of free water by the vampire bat, *Desmodus rotundus*. *Comparative Biochemistry and Physiology Part A: Physiology* 90: 141–146.

You learned at the beginning of the chapter that vampire bats feed once a day. After sunset they fly out, search for a victim, and then return to their roost. This nightly excursion generally takes less than 2 hours. Therefore in a very short time these small animals must take in a large enough volume of their liquid blood diet to supply their energy and water needs for a 24-hour period. How do they do it?

HYPOTHESIS ▶ Vampire bats maximize their food intake by rapidly excreting water, but they then conserve water by producing a highly concentrated urine while digesting their protein meal.

METHOD

1. Offer a colony of captive vampire bats a beef blood meal once a day for 2 hours, to mimic the natural once-a-day feeding behavior of the bats.
2. Do not allow bats access to free water.
3. Measure the daily amount of blood consumed and the time course of subsequent urine volume and concentration.

RESULTS

The table shows the average body mass and average amount of blood consumed by nine vampire bats over a period of 5–8 days.

Average body mass (g)	Average amount of blood consumed (g)
25.0	19.7
26.3	11.3
26.4	13.6
28.6	16.8
29.6	15.7
30.3	17.8
32.4	24.7
36.0	24.4
36.2	18.6

CONCLUSION ▶ In a short daily feeding period, vampire bats consume on average 60% of their body mass.

work with the data

To consume 60% of body mass and still be able to fly, the bats must rapidly excrete a large percentage of the water content of their food. The time course of urine flow and its concentration was measured during and after daily feeding for three vampire bats for 1 week and averaged. Create a double plot of the flow and concentration data as a function of time. (—, no data reported.)

QUESTIONS

1. If you averaged the urine flow rates over the first hour following the beginning of the meal, and you assumed that the total blood intake was 60% of body mass and body mass was 30 g, what percentage of the ingested volume would be excreted in that first hour?
2. Considering that the normal osmolarity of interstitial fluid in a mammal is 300 mosm, what is the maximum concentrating factor in these vampire bats?
3. Three data points are missing in the urine osmolarity curve. Would it be reasonable to plot these data by connecting the 90-min sample and the 330-min sample with a straight line? Why or why not?

A similar **work with the data** exercise may be assigned in **LaunchPad**.

Time after beginning to feed (min)	Average urine flow rate (g/g body mass/hr)	Average urine osmolarity (osm)
10	0.13	0.5
20	0.24	0.25
45	0.16	0.40
90	0.05	0.70
150	0.01	—
210	0.01	—
270	0.005	—
330	0.003	3.3
390	0.02	3.4

countercurrent multiplier The mechanism that increases the concentration of the interstitial fluid in the mammalian kidney through countercurrent flow in the loops of Henle and selective permeability and active transport of ions by segments of the loops of Henle.

The loops of Henle do not themselves produce concentrated urine; rather, they increase the osmolarity of the extracellular fluid in the medulla in a graduated way. In humans, for example, the extracellular fluid at the top of the medulla bordering the cortex will be about 300 mosm/L (the concentration of blood plasma). But at the bottom of the medulla, where the loops of Henle make their hairpin turns, the extracellular fluid can be 1,200 mosm/L (**Focus: Key Figure 51.10**). How do the loops produce this effect?

focus: key figure

Figure 51.10 Concentrating the Urine A countercurrent multiplier mechanism enables the mammalian kidney to produce urine that is far more concentrated than the blood plasma. The composition — but not the concentration — of the filtrate is changed by the proximal convoluted tubule, which reabsorbs valuable molecules (including NaCl). Bulk reabsorption of water follows osmotically. The urine concentration process begins in the thick ascending limb of the loop of Henle, which reabsorbs NaCl but is impermeable to H₂O. This reabsorbed NaCl creates an osmotic differential that pulls water out of the thin descending limb; NaCl also can diffuse into the thin descending limb, making the fluid in that limb more concentrated. Through this continuous process, a concentration gradient in the interstitial fluid of the renal medulla is created as indicated by the gradient of color in the medulla. As urine in the collecting duct passes through this concentration gradient, it can lose water osmotically, becomes more concentrated as indicated by the shading of color, and can become almost as concentrated as the interstitial fluid at the bottom of the renal medulla.

Q: What would be the effect of a drug called a "loop diuretic" that blocks the Na⁺ transport in the thick ascending limb of the loop of Henle?

Animation 51.1 The Mammalian Kidney www.Life11e.com/a51.1

The cells that make up the different segments of the loop of Henle differ anatomically and

functionally. Cells of the descending limb and the initial cells of the ascending limb are thin, with no microvilli and few mitochondria. They are not specialized for transport. Partway up the ascending limb, the cells become specialized for active transport. These cells are thick and have many mitochondria. Accordingly, the segments of the loop of Henle are named the thin descending limb, the thin ascending limb, and the thick ascending limb (see [Figure 51.9C](#)).

The countercurrent multiplier mechanism is best understood by first considering events occurring in the thick ascending limb (see [Figure 51.10](#), note 1). The cells of the thick ascending limb reabsorb Na^+ and Cl^- from the tubule fluid and move it into the interstitial fluid. (In the following discussion, we will distinguish between the two components of extracellular fluid—the blood plasma and the interstitial fluid.) The thick ascending limb is not permeable to water, so the reabsorption of Na^+ and Cl^- from the tubular fluid raises the concentration of those solutes in the surrounding interstitial fluid and decreases the concentration of the tubular fluid entering the distal convoluted tubule.

The thin descending limb, in contrast, is highly permeable to water but not very permeable to Na^+ and Cl^- . Since the local interstitial fluid has been made more concentrated by the Na^+ and Cl^- reabsorbed from the neighboring thick ascending limb, water is withdrawn osmotically from the fluid in the descending limb. Therefore the fluid in the descending limb becomes more concentrated as it flows toward the hairpin turn at the bottom of the renal medulla (see [Figure 51.10](#), note 2).

The thin ascending limb, like the thick ascending limb, is not permeable to water. It is, however, permeable to Na^+ and Cl^- . As the concentrated tubule fluid flows up the thin ascending limb, it is more concentrated than the surrounding interstitial fluid, so Na^+ and Cl^- diffuse out. When the tubule fluid reaches the thick ascending limb, active transport continues to move Na^+ and Cl^- from the tubule fluid to the interstitial fluid.

Because of this countercurrent multiplier mechanism, the tubule fluid reaching the distal convoluted tubule is less concentrated than the blood plasma (see [Figure 51.10](#), note 3), and the solutes that have been left behind in the renal medulla have created a concentration gradient in the interstitial fluid of the medulla (indicated by the background color gradient in [Figure 51.10](#)).

You may wonder why the blood flow through the medulla does not wash out the concentration gradient established by the loops of Henle. The parallel arrangement of the descending and ascending peritubular capillaries in the medulla—the vasa recta—helps preserve the concentration gradient in the medulla. These capillaries are permeable to both salts and water. Therefore as blood flows down the descending limb of the vasa recta into the increasingly concentrated interstitial fluid of the medulla, it loses water and gains solutes. As blood flows up from the bottom of the medulla in the ascending limb of the vasa recta, the opposite happens (water is gained and solutes are lost) because now the blood is more concentrated than the surrounding interstitial fluid (see [Figure 51.10](#), notes 4-6). The dynamics of this countercurrent exchange of salts and water between the blood in the vasa recta and the interstitial fluids result in little net change in the composition of the interstitial fluid in the medulla.

Water permeability of kidney tubules depends on water channels

We have noted that some tubule regions, such as the PCT, are highly permeable to water whereas others, such as the thick ascending limb of the loop of Henle, are impermeable to water. What causes these differences in water permeability in different regions of the nephron? ***Aquaporins** are a class of membrane proteins that form water channels. Regions of the nephron that are highly permeable to water have greater numbers of aquaporins. Thus aquaporins are abundant in kidney PCT cells and in descending limbs of the loops of Henle, but not in the ascending limbs of the loop of Henle.

As an interesting evolutionary note, aquaporins are also important in maintaining water

balance in amphibians. Many amphibians can gain water from a moist substrate because they have aquaporins in the epithelial cells of their belly skin. Thus water can cross their skin into the interstitial fluid by osmosis.

The distal convoluted tubule fine-tunes the composition of the urine

The first portion of the distal convoluted tubule is similar to the thick ascending limb of the loop of Henle. Na^+ and Cl^- are transported out of the tubule fluid, and water cannot follow. As a result, the tubule fluid becomes even more dilute. The later sections of the distal convoluted tubule, however, can be permeable to water, and therefore water can be osmotically drawn from the hypotonic tubule fluid into the interstitial fluid. As the tubule fluid flows through the distal tubule to the collecting duct, it equilibrates with the osmolarity of the blood plasma.

An important function of the distal tubule is the fine-tuning of the ionic composition of the urine. Even though bulk reabsorption of substances such as calcium, phosphate, bicarbonate, and potassium occurs in the proximal convoluted tubule, changes in the concentrations of these substances occur in the distal convoluted tubule. In the case of potassium, for example, if a person is potassium depleted, this ion is reabsorbed in the distal convoluted tubule, but if a person has an abundance of potassium, this ion is secreted in the distal convoluted tubule. As you will see in [Key Concept 51.6](#), this exchange of K^+ is controlled by the hormone aldosterone. Another example is reabsorption of Ca^{2+} in the distal convoluted tubule, which is controlled by the actions of vitamin D. The fine-tuning of urine composition continues in the collecting duct. As you can imagine, the list of ion transporters in the distal convoluted tubule is large.

Urine is concentrated in the collecting duct

The tubule fluid entering the collecting duct is at about the same solute *concentration* as the blood plasma, but its solute *composition* is considerably different from that of the plasma. The major solute in the tubule fluid is now urea, since salts were reabsorbed earlier in the nephron. As the tubule fluid flows down the collecting duct, it loses water osmotically to the interstitial fluid, and that water returns to the circulatory system via the vasa recta (see [Figure 51.10](#), note 4).

The concentration gradient established in the renal medulla by the countercurrent multiplier actions of the loops of Henle creates the osmotic potential that withdraws water from the collecting ducts. The collecting ducts begin in the renal cortex and run through the renal medulla before emptying into the ureter at the tips of the renal pyramids. During this journey, the solute concentration of the surrounding interstitial fluid increases, and more and more water can be absorbed from the urine in the collecting duct. By the time the urine reaches the ureter, it can become greatly concentrated, with urea as the major solute.

As water is withdrawn from the collecting duct, some urea also leaks out into the medullary interstitial fluid, adding to its osmotic potential. This urea diffuses back into the loop of Henle and is returned to the collecting duct. The recycling of urea in the renal medulla contributes significantly to the concentration gradient and therefore the ability of the kidney to concentrate the urine in the collecting duct. The ability of a mammal to concentrate its urine is determined by the maximum concentration gradient it can establish in its renal medulla.

The kidneys help regulate acid-base balance

Besides regulating salt and water balance and excreting nitrogenous wastes, the kidneys have another important role: they regulate the hydrogen ion concentration (the pH) of the extracellular fluids. pH is a critical variable because it influences the structure and function of proteins.

One way to minimize pH changes in a chemical solution is to add a buffer—a substance that can either absorb or release hydrogen ions (see [Key Concept 2.4](#)). The major buffer in the blood is bicarbonate ions (HCO_3^- ; see [Figure 48.14](#)) that are formed from the dissociation of carbonic acid, which in turn is formed by the hydration of CO_2 according to the following equilibrium

reaction:

From this equation, you can see that if excess hydrogen ions are added to this reaction mixture, the reaction will move to the left and absorb the excess H^+ . If hydrogen ions are removed from the reaction mixture, however, the reaction will move to the right and supply more H^+ .

The HCO_3^- buffer system is important for controlling the pH of the blood, and therefore of the interstitial fluids as well, because the reaction can be pushed to the right and pulled to the left physiologically. The lungs control the levels of CO_2 in the blood, thus altering the acid portion of the reaction. CO_2 is considered the acid portion of the reaction because if you add additional CO_2 , the reaction shifts to the right, producing more H^+ ions. The kidneys control the base portion of the reaction by removing H^+ from the blood and returning HCO_3^- to the blood. How does this occur?

HCO_3^- is filtered in the glomerulus and is therefore present in the tubule fluid. As illustrated in [Figure 51.11A](#), tubule cells transport H^+ into the tubule fluid in exchange for Na^+ . In the tubule, the excreted H^+ combines with the filtered HCO_3^- to produce H_2CO_3 that then disassociates into H_2O and CO_2 . The CO_2 diffuses into the tubule cells, where in the presence of the enzyme carbonic anhydrase it produces HCO_3^- that is transported out of the basal end of the cell into the interstitial fluid and thence to the blood. Thus for each H^+ secreted into the tubule fluid, a HCO_3^- ion is released into the blood.

(A) The HCO_3^- buffer system in the renal tubule

(B) Excretion of ammonia

Figure 51.11 The Kidney Excretes Acids and Conserves Bases (A) Bicarbonate ions are filtered out of the blood at the glomerulus, and renal tubule cells secrete hydrogen ions into the tubule fluid. In the renal tubule, the filtered bicarbonate buffers the secreted hydrogen ions and keeps the urine from becoming too acidic. The CO_2 formed by the reaction of bicarbonate and hydrogen ions is converted back to bicarbonate by the renal tubule cells and transported back into the interstitial fluid. (B) Excretion of ammonium ions (NH_4^+) by renal tubule cells is also important for acid-base balance.

Another mechanism for H^+ secretion and HCO_3^- reabsorption involves ammonium ions (NH_4^+). The metabolism of glutamine in tubule cells produces NH_4^+ and HCO_3^- ([Figure 51.11B](#)). The HCO_3^- is reabsorbed into the interstitial fluid. The NH_4^+ is transported into the tubule fluid and combines with Cl^- , which is excreted in the urine. This process results in the addition of a new HCO_3^- ion to the blood. The NH_4^+ is transported into the tubules by means of an NH_4^+ transporter.

Kidney failure is treated with dialysis

Loss of kidney function (renal failure) results in the retention of salts and water (hence high blood pressure), retention of urea (uremic poisoning), and a decreasing pH (acidosis). A person who suffers complete renal failure will die within 2 weeks if not treated. A drastic but highly successful treatment is kidney transplant, but it is usually necessary to sustain a patient for considerable time while waiting for a kidney to become available. Therefore artificial kidneys, or renal dialysis machines, are essential modes of treatment.

In a dialysis machine, the patient's blood flows through many small channels made of semipermeable membranes ([Figure 51.12](#)). A dialysis solution flows on the other side of these membranes, through which small molecules can diffuse. Molecules and ions diffuse from an area of higher concentration to an area of lower concentration, so the composition of the dialysis fluid is crucial. The concentrations of the molecules or ions that need to be conserved must be at the same concentration in the dialysis fluid as they are in the blood. The concentrations of molecules and ions that need to be removed from the blood are zero in the dialysis fluid. The total osmotic potential of the dialysis fluid must equal that of the blood plasma.

Figure 51.12 Renal Dialysis Patients with kidney failure can have their blood cleansed of wastes by renal dialysis machines. Blood flows through channels of semipermeable membranes that allow diffusion of waste molecules from the blood to a dialysis fluid.

About 500 mL of the patient's blood is in the dialysis machine at any one time, and the unit processes several hundred milliliters of blood per minute. A patient with no kidney function must be on the dialysis machine for 4-6 hours three times a week.

51.5 recap

The anatomical organization of nephrons makes it possible for the mammalian kidney to produce a urine more concentrated than the blood, thereby conserving water to maintain extracellular fluid volume. Bulk reabsorption of salts, other valuable solutes, and water takes place in the proximal convoluted tubule. The loops of Henle act as a countercurrent multiplier, creating a concentration gradient of the interstitial fluids in the renal medulla. Collecting ducts run through the renal medulla and lose water osmotically to the surrounding interstitial fluids, concentrating the urine. The renal tubules contribute to acid-base balance by excreting H^+ ions.

learning outcomes

You should be able to:

- Describe the internal organization of the mammalian kidney.
 - Describe the mechanism whereby most of the glomerular filtrate is reabsorbed in the proximal convoluted tubule.
 - Describe how the loop of Henle maintains a concentration gradient in the extracellular fluid of the medulla of the kidney.
 - Describe how the mammalian excretory system is involved in regulating pH of the extracellular fluid.
-
1. If you could measure the concentration of mitochondria in mammalian kidney tissues, where would you find the highest concentration, the lowest concentration, and an intermediate concentration? Explain your answer.
 2. How do the loops of Henle act as a countercurrent multiplier?
 3. If you compared a water rat and a desert rat of the same size, how would you expect their kidneys to differ in anatomical structure? Explain your answer.
 4. How does the active secretion of H^+ ions by the renal tubule cells result in an increase in the bicarbonate concentration in the blood?

The kidneys contribute to homeostasis in several ways, including regulating extracellular fluid volume, maintaining the osmotic concentration and ionic composition of the extracellular fluid, and regulating pH. As you will see next, the kidneys also play a major role in regulating blood pressure.

***connect the concepts** As explained in [Key Concept 6.3](#), water does not cross cell membranes easily, but aquapo-rins are protein channels that make cells permeable to water.

51.6 Kidney Function Is Regulated

Several regulatory mechanisms act on the kidneys to maintain blood pressure, blood osmolarity, and blood composition. We will discuss these mechanisms separately, but keep in mind that they are always working together.

focus your learning

Circulating renin initiates activation of angiotensin, which acts in several ways to increase blood pressure.

The kidney autoregulates its vascular resistance to maintain constancy of glomerular filtration rate.

Antidiuretic hormone (ADH) controls urine concentration in response to blood pressure and blood osmolarity.

Glomerular filtration rate is regulated

If the kidneys stop filtering blood, they cannot accomplish any of their functions. The maintenance of a constant [glomerular filtration rate \(GFR\)](#) depends on an adequate blood supply to the kidneys at an adequate blood pressure. Renal arteries usually deliver blood to the kidneys at high pressure because they are early branches off the aorta. In addition, autoregulatory mechanisms ensure adequate blood supply and blood pressure for kidney function regardless of what is happening elsewhere in the body. The kidney's autoregulatory adjustments compensate for decreases in cardiac output or decreases in blood pressure so that the GFR remains constant.

glomerular filtration rate (GFR) The rate at which the blood is filtered in the glomeruli of the kidney.

One autoregulatory mechanism is the dilation (expansion) of the afferent renal arterioles when blood pressure falls. This dilation decreases the resistance in the arterioles and helps maintain blood pressure in the glomerulus. If arteriole dilation does not keep the GFR from falling, the kidney releases an enzyme, [renin](#), into the blood. Renin converts a circulating protein, angiotensinogen, into angiotensin I, which is then acted on by angiotensin-converting enzyme (ACE) in the lungs and other tissues to form the active hormone angiotensin II, or simply [angiotensin](#) ([Figure 51.13](#)). Angiotensin has several effects that help restore the GFR to normal:

renin An enzyme released from the kidneys in response to a drop in the glomerular filtration rate. Together with angiotensin converting enzyme, converts an inactive protein in the blood into angiotensin.

angiotensin (an' jee oh ten' sin) A peptide hormone that raises blood pressure by causing peripheral vessels to constrict. Also maintains glomerular filtration by constricting efferent vessels and stimulates thirst and the release of aldosterone.

Figure 51.13 The Renin-Angiotensin-Aldosterone System Helps Regulate GFR
 When glomerular filtration rate (GFR) falls, tubular fluid flows more slowly through the loops of Henle, more NaCl is reabsorbed from the thick ascending limb, and the fluid reaching the distal convoluted tubule is more dilute. Dilute fluid in the distal convoluted tubule (where it comes into contact with the afferent and efferent glomerular arterioles) stimulates release of the enzyme renin into the circulation. Renin starts a cascade of events that work together to raise blood volume, blood pressure, and GFR.

Activity 51.4 Kidney Regulation Simulation www.Life11e.com/ac51.4

It constricts the efferent renal arterioles, raising the resistance for blood leaving the glomerulus. Like putting a finger over the end of a garden hose, this restriction of drainage elevates blood pressure in the glomerular capillaries.

It constricts peripheral blood vessels all over the body, an action that elevates blood pressure.

It stimulates the adrenal cortex to release the hormone **aldosterone**. Aldosterone stimulates sodium reabsorption by the kidney, making its reabsorption of water more effective. Enhanced water reabsorption helps maintain blood volume and therefore blood pressure.

It acts on the brain to stimulate thirst. Increased water intake in response to thirst increases blood volume and blood pressure.

aldosterone (al dohs' ter own) A steroid hormone produced in the adrenal cortex of mammals. Promotes secretion of potassium and reabsorption of sodium in the kidney.

Thus the renin-angiotensin-aldosterone system, or RAAS, coordinates many responses to maintain blood pressure and kidney function.

Regulation of GFR uses feedback information from the distal tubule

A remarkable anatomical feature of the nephron is that where its renal tubule returns to the cortex and becomes the distal convoluted tubule, it makes contact with the afferent and efferent arterioles of its glomerulus. At this location the cells of the tubule are modified to form a structure called the macula densa (see [Figure 51.13](#)), and the arteriole cells are also modified and are called juxtaglomerular cells. The macula densa cells sense the concentration of NaCl in the fluid entering the distal convoluted tubule. If GFR is high, flow through the loop of Henle is high and the cells of the thick ascending limb cannot reabsorb all of the NaCl passing through it. If GFR is low, flow through the loop of Henle is slower and the cells of the thick ascending limb can reabsorb more of the NaCl. If the NaCl level in the distal convoluted tubule drops too low, the macula densa cells signal the juxtaglomerular cells to release renin and trigger the RAAS response. Thus the concentration of NaCl in the fluid passing over the macula densa is a function of GFR and is information that enables fine control of the RAAS system.

Blood osmolarity and blood pressure are regulated by ADH

Cells in the hypothalamus can stimulate the release of a hormone called [antidiuretic hormone \(ADH\)](#), also called vasopressin) from the posterior pituitary. ADH stimulates cells of the collecting duct to insert aquaporins (water channels) into their cell membranes. The aquaporins increase the permeability of these membranes to water, and therefore more water is reabsorbed from the collecting duct fluid into the interstitial fluid of the renal medulla. The higher the circulating levels of ADH, the greater the number of aquaporins. Various factors can stimulate or inhibit the release of ADH. Of key importance to kidney function are (1) osmoreceptors that monitor blood osmolarity and (2) stretch receptors that monitor blood pressure ([Figure 51.14](#)).

antidiuretic hormone (ADH) See vasopressin.
--

Figure 51.14 Antidiuretic Hormone Increases Blood Pressure and Promotes Water Reabsorption ADH is produced by neurons in the hypothalamus and released from nerve endings in the posterior pituitary. The release of ADH is stimulated by hypothalamic osmoreceptors and inhibited by stretch receptors in the great arteries. Red lines indicate inhibitory actions; green lines show stimulatory actions.

Osmoreceptor neurons in the hypothalamus are activated by a rise in blood osmolarity, and they increase the release of ADH. ADH helps regulate blood osmolarity by controlling water reabsorption. The osmoreceptors also stimulate thirst. The resulting water retention and water intake dilute the blood as they expand blood volume.

Stretch receptors in the walls of the aorta and the carotid arteries (see [Figure 49.19](#)) that detect an increase in blood pressure will *inhibit* the release of ADH. With less circulating ADH, less water is reabsorbed, which increases urine volume and decreases blood volume, hence lowering blood pressure.

If blood pressure falls, as when you lose blood volume through hemorrhage or excessive evaporative water loss, activity of the stretch receptors in the aorta and carotid arteries decreases. Input via cranial nerves to the hypothalamus from these receptors inhibits the release of ADH, so when the firing rates of these stretch receptors fall, ADH release increases. More ADH results in more efficient water reabsorption and therefore a protection of blood volume and blood pressure.

Alcohol inhibits ADH release, explaining why excessive beer drinking leads to excessive urination and dehydration, which contributes to the symptoms of a hangover.

As already mentioned, the presence of aquaporins in cell membranes determines their water

permeability. Aquaporins play an important and unique role in the collecting duct. Several members of the aquaporin family of water channels are found in the cell membranes of the collecting duct cells. At least two aquaporins (AQP-3 and AQP-4) are localized in the basolateral membranes (facing the blood vessels). A different aquaporin, AQP-2, is found in the apical cell membranes (facing into the tubule). The presence of AQP-2 in these membranes is controlled by ADH ([Figure 51.15](#)).

Figure 51.15 ADH Induces Insertion of Aquaporins into Cell Membranes

Original Paper: Nielsen, S., C. L. Chou, D. Marples, E. I. Christensen, B. K. Kishore and M. A. Knepper. 1995. Vasopressin increases water permeability of kidney collecting duct by inducing translocation of aquaporin-CD water channels to plasma membrane. *Proceedings of the National Academy of Sciences USA* 92: 1013–1017.

Aquaporin proteins make some regions of renal tubules permeable to water. One aquaporin, AQP-2, is responsible for the permeability of the collecting duct cells. M. A. Knepper and colleagues did an experiment to find out how antidiuretic hormone acts on these proteins to control the level of permeability in renal cells.

HYPOTHESIS ▶ Antidiuretic hormone (ADH) controls the location of aquaporin proteins.

METHOD

1. Isolate collecting ducts from rat kidney.
2. Use immunochemical staining to localize the AQP-2 aquaporins in collecting duct cells both with and without the presence of ADH. Also localize the aquaporins after ADH is applied and then washed away.

3. Measure the water permeability of the collecting duct cells under the same three conditions.

RESULTS

CONCLUSION ▶ In the absence of ADH, AQP-2 is sequestered intracellularly. When ADH is present, AQP-2 channels are inserted into cell membranes, making the cells more permeable to water.

When ADH levels are low, such as when a person is well hydrated, most of the AQP-2 protein is sequestered in the membranes of intracellular vesicles, and the collecting duct permeability is low. A rise in ADH levels stimulates the insertion of these vesicles along with their AQP-2 channels into the apical cell membranes. As a result, the membranes become more permeable to water. Water that enters the collecting duct cells passes into the interstitial fluid through the aquaporins in the basolateral membranes. ADH also stimulates the synthesis of new AQP-2 proteins. Thus circulating ADH controls the number of AQP-2 water channels in the cell membranes of the collecting duct cells, and therefore the permeability of the collecting duct to water.

The heart produces a hormone that helps lower blood pressure

You may not think of the heart as an endocrine organ, but it is. When blood volume is high, blood pressure is high, putting strain on the heart. Under these conditions, the increased venous return stretches the atria of the heart. When the atrial muscle fibers are over-stretched, they release a peptide hormone called [atrial natriuretic peptide \(ANP\)](#). This peptide hormone enters the circulation, and in the kidney it decreases the reabsorption of sodium. If less sodium is reabsorbed, less water is reabsorbed, and more passes into the urine. Thus ANP has the effect of lowering blood volume and therefore blood pressure.

atrial natriuretic peptide (ANP) A hormone released by the atrial muscle fibers of the heart when they are overly stretched, which decreases reabsorption of sodium by the kidney and thus blood volume.

51.6 recap

Glomerular filtration is essential for kidney function and is sustained by autoregulatory mechanisms. These autoregulatory mechanisms include changes in dilation and constriction of the glomerular afferent arterioles and hormonal control over constriction of the efferent glomerular arteriole mediated by the renin-angiotensin-aldosterone system (RAAS). Angiotensin controls the release of aldosterone, which controls sodium reabsorption. Sensors that monitor blood pressure and blood osmolarity stimulate or inhibit the release of ADH, which controls the water permeability of the collecting duct.

learning outcomes

You should be able to:

- Describe how renin, angiotensin, and aldosterone affect glomerular filtration rate and blood pressure.
- Given an event that lowers blood pressure, predict the response of the renin-angiotensin-aldosterone system.
- Describe ADH's role in regulating kidney function in response to changes in blood osmolarity or blood pressure.

- [1.](#) What are the mechanisms whereby the afferent and efferent arterioles regulate the GFR, and how are those responses controlled?
- [2.](#) Aldosterone stimulates activity of the Na^+/K^+ exchangers in the distal convoluted tubule

and the initial segments of the collecting ducts. Aldosterone release is triggered by angiotensin. Given this information, what is the significance of the fact that the Na^+/K^+ exchanger in the tubule cells secretes two K^+ ions for every three Na^+ ions it reabsorbs?

3. If you drank a lot of salty chicken broth that had an osmotic concentration of 300 mosm/L, what two mechanisms would play roles in the response of your kidneys to excrete the excess fluid volume and excess Na^+ ? Explain your answer.

investigatinglife

QA How does the excretory system of vampire bats process their high-protein liquid diet?

As we described in the opening story, vampire bats conserve water by producing urine that can be as much as 15 times more concentrated than their blood. For comparison, the maximum urine concentration of humans is about four times that of the blood.

Recall from [Key Concept 51.5](#) that the mammalian body's ability to produce concentrated urine depends on the concentration gradient set up in the renal medulla by the loops of Henle. An important adaptation for increasing the concentration gradient is to increase the lengths of the loops of Henle relative to overall kidney size. Some tiny desert gerbils, for example, have such extremely long loops of Henle that the renal pyramid (each of the rodent kidneys has only one, in contrast to humans) extends far out of the concave surface of the kidney and into the ureter ([Figure 51.16](#)). The large concentration gradient that results draws most of the water out of the urine as it passes down the collecting duct. Desert gerbils are so effective in conserving water that they can survive on the water released by the metabolism of their food.

(A) Desert gerbil

Renal cortex Renal medulla Loops of Henle (many)

(B) Laboratory rat

Loops of Henle Renal medulla

Figure 51.16 The Ability to Concentrate The ability of the mammalian kidney to concentrate urine depends on the lengths of its loops of Henle relative to the overall size of the kidney. (A) The kidney of a desert gerbil has a single renal pyramid with loops of Henle so long that the pyramid extends far into the ureter (ureter not shown). (B) An ordinary laboratory rat has much shorter loops of Henle.

Q: Do you think the vampire bat has loops of Henle resembling those of the laboratory rat or the desert gerbil?

The vampire bat kidney is also particularly good at concentrating urea. Within minutes after feeding, the urea concentration in its urine can increase by more than 500-fold.

Future directions

Understanding the diverse mechanisms whereby physiological systems are controlled and regulated can contribute to the discovery and development of new pharmaceuticals. The renal system is an example. Many diseases involve problems with salt and water balance. A common problem is water retention. A large number of drugs have been developed that increase the excretion of water in urine, such as occurs naturally in vampire bats. These drugs are called diuretics, and since they act through different mechanisms, they have different effects on Na^+ , K^+ , and Ca^{2+} levels in the blood, which can cause serious side effects. Excessive loss of K^+ , for example, can lead to heart arrhythmia, muscle weakness, and paralysis. Excessive retention of K^+ can also lead to heart arrhythmia, along with muscle cramps and paralysis. Loss of too much Na^+ can result in central nervous system deficits. Too much Ca^{2+} has many negative side effects, ranging from depression and fatigue to vomiting and gout. Thus it is important to understand how drugs work on physiological systems, to avoid negative side effects.

► 51.1 Excretory Systems Regulate Osmotic and Ionic Concentrations

- **Excretory systems** maintain the **osmolarity** and volume of the extracellular fluids and eliminate the waste products of nitrogen metabolism through the processes of filtration, reabsorption, and secretion. **Urine** is the output of excretory systems.
- There is no active transport of water, so water must be moved across membranes by a difference in either osmolarity or pressure.
- Water enters and leaves cells by osmosis. To achieve cellular water balance, animals must maintain the osmolarity of their extracellular fluids within an acceptable range.
- Marine animals can be **osmoconformers** or **osmoregulators**. Freshwater animals must be osmoregulators and must continually excrete water and conserve salts. Terrestrial animals are osmoregulators, but the nature of their regulation depends on environment and lifestyle. **Review Figure 51.1**
- Apart from regulating osmolarity of cells and extracellular fluids, animals must also regulate their ionic composition by conserving some ions and secreting others. Salt glands are adaptations for secretion of NaCl. **Review Figure 51.2**

► 51.2 Animals Excrete Nitrogen as Ammonia, Urea, or Uric Acid

- Aquatic animals that breathe water can eliminate nitrogenous wastes such as **ammonia** by diffusion across their gill membranes. Terrestrial animals and some aquatic animals must detoxify ammonia by converting it to **urea** or **uric acid** before excretion. **Review Figure 51.3**
- Depending on the form in which they excrete their nitrogenous wastes, animals are classified as **ammonotelic**, **ureotelic**, or **uricotelic**.

► 51.3 Invertebrate Excretory Systems Use Filtration, Secretion, and Reabsorption

- The **protonephridia** of flatworms consist of flame cells and excretory tubules. Extracellular fluid is filtered into the tubules, which process the filtrate to produce dilute urine. **Review Figure 51.4**
- In annelid worms, blood pressure causes filtration of the blood across capillary walls. The filtrate enters the coelomic cavity, where it is taken up by **metanephridia**, which alter the composition of the filtrate by active transport mechanisms. **Review Figure 51.5, Activity 51.1**
- The **Malpighian tubules** of insects receive ions and nitrogenous wastes by active transport across the tubule cells. Water follows by osmosis. Ions and water are reabsorbed from the rectum, so the insect excretes semisolid wastes. **Review Figure 51.6**

► 51.4 The Nephron Is the Basic Functional Unit of Vertebrate Excretory Systems

- Marine bony fishes produce little urine. Cartilaginous fishes retain urea and TMAO, so the osmolarity of their body fluids remains close to that of seawater.
- Reptiles, including birds, have skin with low water permeability and excrete nitrogenous

wastes as uric acid in a semisolid form.

- Mammals produce urine that is more concentrated than their extracellular fluids.
- The **nephron**, the functional unit of the vertebrate **kidney**, consists of a **glomerulus**, in which blood is filtered, a **renal tubule**, which use processes of active secretion and reabsorption to convert the glomerular filtrate into urine to be excreted, and a system of **peritubular capillaries**, which surround the tubule and support its functions of secretion and reabsorption. **Review** [Figures 51.7](#), [Activity 51.2](#)

► 51.5 The Mammalian Kidney Can Produce Concentrated Urine

- The concentrating ability of the mammalian kidney is a function of its anatomy, which enables countercurrent exchange.
- The glomeruli and the **proximal** and **distal convoluted tubules** are located in the **cortex** of the kidney. Certain molecules are actively reabsorbed from the glomerular filtrate by the tubule cells, and other molecules are actively secreted. Straight sections of renal tubules called **loops of Henle** and **collecting ducts** are arranged in parallel in the **medulla** of the kidney. **Review** [Figure 51.9](#), [Activity 51.3](#)
- Salts, water, and valuable molecules such as glucose and amino acids are reabsorbed in the proximal convoluted tubule without the renal filtrate becoming more concentrated, although its composition changes.
- The loops of Henle create a concentration gradient in the interstitial fluid of the renal medulla by a **countercurrent multiplier** mechanism. Urine flowing down the collecting ducts to the **ureter** is concentrated by the osmotic reabsorption of water caused by the concentration gradient in the surrounding interstitial fluid. **Review Focus: Key** [Figure 51.10](#), [Animation 51.1](#)
- Hydrogen ions secreted by the renal tubules are buffered in the urine by bicarbonate and other chemical buffering systems. **Review** [Figure 51.11](#)

► 51.6 Kidney Function Is Regulated

- Kidney function in mammals is controlled by autoregulatory mechanisms that maintain a constant high **glomerular filtration rate (GFR)** even if blood pressure varies.
- The RAAS is an important autoregulatory mechanism. **Renin** is released by the kidney when blood pressure falls. Renin activates **angiotensin**, which causes the constriction of efferent glomerular arterioles and peripheral blood vessels, causes the release of **aldosterone** (which enhances water reabsorption), and stimulates thirst. **Review** [Figure 51.13](#), [Activity 51.4](#)
- Changes in blood pressure and osmolarity influence the release of **antidiuretic hormone (ADH)**, which controls the permeability of the collecting duct to water and therefore the amount of water that is reabsorbed from the urine. ADH stimulates the expression of and controls the intracellular location of aquaporins, which serve as water channels in the membranes of collecting duct cells. **Review** [Figures 51.14](#), [51.15](#)
- When the volume of blood returning to the heart increases and stretches the atrial walls, **atrial natriuretic peptide (ANP)** is released, which causes increased excretion of salt and water.

See [Activity 51.5](#) **for a review of the major human organ systems.**

Review

1.5 As the tubular fluid passes down the collecting duct, water can be reabsorbed into the extracellular fluid to produce a more concentrated urine in the tubule.

Original Paper: Schmidt-Nielsen, B. and R. O'Dell. 1961. Structure and concentrating mechanism in the mammalian kidney. *American Journal of Physiology* 200: 1119-1124.

The ability of a mammalian kidney to produce concentrated urine is directly related to the countercurrent multiplier mechanism found in the loops of Henle. Because of the way this mechanism works, it could be hypothesized that the longer the loops of Henle, the more concentrated the urine can become. Since bigger kidneys should have the longest loops, a large mammal, such as an elephant, should be able to produce much more concentrated urine than a small mammal, like a shrew. However, some of the mammals that live in the driest conditions on Earth are very small. How can these small mammals conserve water by producing highly concentrated urine with such tiny kidneys?

To account for body size, scientists refined their hypothesis by saying that it wasn't just the total length of the loops of Henle, but the "relative" length compared with the rest of the kidney. The loops of Henle are found only in the medulla of the kidney, so the loops can be only as long as the medulla is thick. To normalize the data across different-sized mammals, a new measurement called the relative medullary thickness (RMT) was conceived. The RMT is equal to the thickness of the medulla divided by width $\times$ length $\times$ thickness of the whole kidney.

On further study, it was also noticed that in many species not all of the loops of Henle extend the full length of the medulla. Some are shorter than others. This presented a second hypothesis, namely that the ability to concentrate urine could be related to the number of long loops of Henle compared with short loops of Henle. In other words, the higher the percent of long loops to short, the higher the possible concentration of urine.

To gather evidence in support of one hypothesis over the other, scientists performed many measurements on various-sized mammals from different environments. The scientists deprived the mammals of water to find the limit of each mammal's ability to concentrate urine. A test called the freezing point depression (FPD) was used to measure urine concentration. Fresh water freezes at 0°C, but the more solutes that are added to the water, the lower the temperature must be to get the solution to freeze. So the FPD of urine samples reveals their concentrations. The results of all of these tests are seen in the table.

Animal	Percent long loops of Henle	RMT	FPD (°C)
Human	14	3	2.6
Pig	3	1.6	2
Dog	100	4.3	4.85
Cat	100	4.8	5.8
Beaver	0	1.3	0.96
Lab rat	28	5.8	4.85
Sand rat	100	10.7	9.2
Kangaroo rat	27	8.5	10.4
Jerboa	33	9.3	12

Questions

1. Is the RMT a good predictor of an animal's ability to concentrate urine? To answer this, plot the RMT versus FPD.
2. Are animals with a higher percent of long loops of Henle more capable of producing concentrated urine? To answer this, plot the percent long loops of Henle versus FPD.
3. Is the percent of long loops of Henle or RMT the better predictor of an animal's ability to concentrate urine? Explain your answer.

An Instinct to Learn

A springtime joy is hearing birds sing. Why do they do it? Male songbirds use species-specific song to compete with other males for territory. They also sing to attract mates. Females may not sing, but they recognize the songs of their own species. Males of most species, such as the white-crowned sparrow (*Zonotrichia leucophrys*), must learn their song, but *what* they can learn is influenced by their genes, and when they can learn it is influenced by their physiology. A hatchling in the nest hears his father and other white-crowned sparrows singing. He also hears the songs of many other bird species. He does not sing until he approaches sexual maturity almost a year later, and when he does, he sings his father's type of song and not that of other species. His first attempts at song are poor, but by trial and error he gradually matches his song to the one stored in his memory, even though other species are singing in his environment. His singing talent depends on two critical conditions: he must hear his species-specific song in the first 2 months of life, and he must be able to hear himself as he develops his song. These are both learning experiences, but the bird's genes play an important role too.

Male white-crowned sparrows raised alone in the laboratory and exposed to recordings of unrelated species will not learn any of those song templates even if they are played over and over. But if in that cacophony of songs, a bird's species-specific song is played just a few times, he will sing that song the following spring. Thus male white-crowned sparrows must learn their song, but a genetic predisposition ensures that they learn the song of their own species.

An important reason why males learn only their species-specific song is that the females also listen to their father's songs when they are nestlings. When they mature, they choose mates that sing like their fathers did. But how does one female choose her specific mate? There is variation in male songs, and some components of songs seem sexier than others. Also, the way the songs are performed may differ among individuals and in different social contexts. As in humans, variability surely plays a role in mate choice.

QA How does social context influence the learning and expression of birdsong?

52.1 Ethology Led to Modern Behavioral Biology

Humans have studied animal behavior since prehistoric times. Understanding the habits of potential prey, as well as those of their predators, was of great value to hunters. Appreciation of behavioral traits led to the domestication of animal species. Accounts of animal behaviors such as seasonal appearances and disappearances, mating displays, aggression, prey capture, parental care, and communication are found throughout recorded history. Yet the scientific study of animal behavior did not truly get under way until the early 1900s.

focus your learning

Ethology is the study of natural behaviors in natural species.

Behaviors have proximate and ultimate causes.

Conditioned reflexes are a simple behavioral mechanism

In the late 1800s the Russian physiologist Ivan Pavlov used dogs to study the neural control of digestive juice secretion. Of course his dogs salivated when they smelled food, but Pavlov observed that they also salivated whenever the technician who routinely fed the dogs entered the room—even when no food was present. Following up this observation, Pavlov substituted a sound stimulus for the technician; a metronome ticked while the dogs were fed. After several trials, the dogs salivated when they heard the metronome, even if no food was offered.

Salivation in response to the sight, smell, or taste of food is a natural reflex response to a stimulus, but salivation in response to a sound was a learned response. The pairing of a sound with the experience of receiving food conditioned the dogs' nervous systems to generate a response, which Pavlov dubbed the **conditioned reflex** (Figure 52.1). The natural stimulus—food in this case—became known as the unconditioned stimulus, and the unnatural stimulus was termed the conditioned stimulus. Pavlov received a Nobel prize in 1904 for his work showing that a simple behavior controlled by the nervous system could be modified through experience. This work stimulated much new research because Pavlov had developed an experimental model of learning.

conditioned reflex A form of associative learning first described by Ivan Pavlov, in which a natural response (such as salivation in response to food) becomes associated with a normally unrelated stimulus (such as the sound of a bell or a metronome).

(A) Before conditioning

(B) Conditioning

(C) After conditioning

Figure 52.1 The Conditioned Reflex (A) Prior to conditioning, there is no response to the neutral stimulus. Ivan Pavlov discovered that when a normal response is paired with an artificial or neutral stimulus (B), an animal learns to produce the response even when only the artificial stimulus is presented (C).

Going beyond the conditioning of autonomic reflexes, the psychologist B. F. Skinner showed that many behaviors could become a conditioned response to a stimulus if a reward was associated with the action and the stimulus. A rat, for example, could be conditioned to press a lever in response to a stimulus if it got a reward when it pressed the lever. Because the animal

was conditioned to perform an *operation* on its environment, this experimental protocol was called **operant conditioning** and became another model of learning.

operant conditioning Using a reward or a punishment to control the expression of a behavior by an animal in response to an unrelated stimulus.

The experimental approaches to behavior initiated by Pavlov and Skinner stimulated a lot of research on animal behavior, but the focus of that research was mostly controlled laboratory experiments on learning and memory in only a few species— mostly the white rat. This field of animal behavior became known as **behaviorism**.

behaviorism One of two classical approaches to the study of proximate causes of animal behavior, derived from the discoveries of Ivan Pavlov and focused on laboratory studies. (Compare with ethology.)

Ethologists focused on the behavior of animals in their natural environment

An alternative approach to the study of animal behavior arose at the same time as behaviorism and focused on the various behaviors of animals in their natural environment. This field of study became known as **ethology** (Greek *ethos*, “character,” + *logos*, “study”). Ethologists were interested in a wide variety of species, their evolutionary relationships, and the ways in which their behaviors were adapted to their environments. The leaders of the ethology movement were Karl von Frisch, who discovered the dance language of honey bees; Konrad Lorenz, who discovered that the strong bond between parent and offspring develops during a “critical period” following birth; and Niko Tinbergen, who studied inborn patterns of behavior commonly known as instincts. These three scientists shared the Nobel Prize in 1973 for “their discoveries concerning organization and elicitation of individual and social behavior patterns.” Their work laid the foundation for modern research on animal behavior.

ethology [Gk. *ethos*: character + *logos*: study] An approach to the study of animal behavior that focuses on studying many species in natural environments and addresses questions about the evolution of behavior. (Compare with behaviorism.)

Ethologists were mainly interested in species-specific or instinctive behaviors that therefore had to have genetic components. Behaviors were thought to be genetically determined if they:

- are performed without learning.
- are stereotypic (that is, they are performed the same way each time).
- cannot be modified by learning.

The ethologists called such behaviors **fixed action patterns**.

fixed action pattern In ethology, a genetically determined behavior that is performed without learning, stereotypic (performed the same way each time), and not modifiable by learning.

Ethologists performed **deprivation experiments** to demonstrate the genetic determination of

a behavior. They raised animals in an environment devoid of opportunities to learn their species-specific behavior, and then looked for the expression of that behavior. The web spinning of a spider is an example of a natural deprivation experiment. The parents of a young spider die before it hatches, and in a seasonal environment it has no model webs to copy when it spins its first web, which requires thousands of stereotyped sequential movements. Yet a young spider creates a perfect, species-specific web the first and every time it spins a web. Thus the information for the web spinning behavior has to be genetically programmed into its nervous system.

deprivation experiments Raising an animal in an environment devoid of behavioral models from which it could learn a species specific behavior to see if the behavior is still expressed.

Fixed action patterns are usually responses to specific stimuli. The ethologists carefully characterized such stimuli, which they called **releasers**. In general, releasers are simple subsets of the information available in the environment. For example, Tinbergen studied the begging behavior of gull chicks. Adult gulls have a red dot on their lower bill. When a parent returns to the nest to feed its chicks, the chicks peck on the red dot, which stimulates the parent to regurgitate food (**Figure 52.2A**). Experimenters investigated what stimulated the chicks to peck their parents' bills. Models of gull heads of different shapes and colors were tested (**Figure 52.2B**), as were models of a beak without a head. The results showed that the red dot was necessary for the release of chick pecking behavior. In fact, a pencil with a red eraser elicited a more robust pecking response than an accurate model of a gull head without a red dot.

releaser Sensory stimulus that triggers performance of a stereotyped behavior pattern.

Figure 52.2 Releasing a Fixed Action Pattern (A) In many gull species, chicks instinctively peck at the red dot on the parent's lower bill, a behavior that induces the parent to regurgitate food into the chick's mouth. **(B)** Tinbergen's work showed that the red dot on the parent's lower bill is the critical component that releases the pecking response.

Q: Why do you think sign stimuli are rather simple components of all of the sensory information available?

Ethologists probed the causes of behavior

The ethologists demonstrated the genetic basis for fixed action patterns by interbreeding closely related species. Konrad Lorenz studied the courtship behaviors of different species of dabbling

ducks. Some of these species, such as mallards, teals, pintails, and gadwalls, are closely related and can interbreed, but they rarely do so in nature. Each male duck performs a courtship display consisting of a precise series of movements that is typical of his species. A female is not likely to accept him unless the entire display is successfully and correctly completed.

Lorenz crossbred these duck species and found that the hybrid offspring expressed some elements of each parent's courtship display, but in novel combinations. Furthermore, Lorenz observed that hybrids sometimes exhibited display elements that were not in the repertoire of either parent species but were seen in other dabbling duck species. Lorenz's interbreeding studies demonstrated that the stereotypic motor patterns of the courtship displays are inherited. The observation that females were not interested in males performing hybrid displays was evidence that sexual selection had shaped these genetically determined behaviors to be

***reproductive isolating mechanisms.**

The ethologists laid the foundation for the application of modern biological methods to the study of animal behavior. Tinbergen outlined the challenges for investigators as four questions:

- . *Causation*: What is the mechanism underlying the behavior, and how can the relationship between mechanisms and behavior be modified by learning?
- . *Development*: What experiences are necessary for a behavior to be displayed, and how does the behavior change with age?
- . *Function*: How does the behavior affect the animal's chances for survival and reproduction?
- . *Evolution*: How does the behavior compare with similar behaviors in related species, and how might it have evolved?

The first two questions refer to the **proximate causes** of behavior: the immediate genetic, physiological, neurological, and developmental mechanisms that determine how an individual is behaving at a particular time. The third and fourth questions refer to the **ultimate causes** of behavior: the evolutionary processes that produced the animal's capacity and tendency to behave in particular ways. In the sections that follow, we will describe many experiments on animal behavior. For each one, ask yourself which of Tinbergen's four questions it addresses and whether it focuses on proximate or ultimate causes of behavior.

proximate causes The immediate genetic, physiological, neurological, and developmental mechanisms responsible for a behavior or morphology. (Contrast with ultimate causes.)

ultimate causes In ethology, the evolutionary processes that produce an animal's capacity and tendency to behave in particular ways. (Contrast with proximate causes.)

52.1 recap

Early scientific studies of animal behavior took two approaches. Behaviorists focused on the study of conditioned behavior in a few species of laboratory animals and asked questions about learning. Ethologists studied genetically determined behavior in many species in their natural environments and asked evolutionary questions.

learning outcomes

You should be able to:

- Differentiate between behaviorism and ethology.
- Explain the significance of deprivation experiments.

- Explain what proximate and ultimate causes of behavior are, using examples.
-

1. What distinguishes fixed action patterns from behaviors resulting from Pavlovian or operant conditioning?
 2. What variables might account for a genetically determined behavior not being expressed in a deprivation experiment?
 3. What are proximate and ultimate causes of mating-display behavior?
-

The work of the ethologists left no doubt that behavior can be genetically determined, but how? Genes code for proteins, whereas behaviors are highly complex traits involving sensory input and intricate patterns of control over responses to that input. Is it reasonable to think that a single gene can have a specific effect on a behavior?

***connect the concepts** The evolution of populations into different species occurs when hybrids of the two populations have lower fitness. In those cases, selection favors mechanisms that prevent hybridization, and behavioral reproductive isolating mechanisms are the most common, as described in [Key Concept 23.4](#).

52.2 Behavior Can Be Genetically Determined

The work of the ethologists showed the strong genetic basis for most animal behaviors. Of course, *most* animals are insects and other invertebrates, and even among the vertebrates *most* are not mammals, let alone primates. So even though the controversy over the relative influences of nature versus nurture in human behavior has raged for many years, the dominant role played by genes in shaping behavior is amply documented by research on other species. Genetically determined complex behaviors such as the web spinning of spiders or the mating behaviors of dabbling ducks mentioned above must surely depend on many genes. Yet with the rapid development of genomic analytical technologies, comparisons of genomes of animals with different behavioral phenotypes are producing many examples of single gene alterations that produce behavioral differences.

focus your learning

Even single genes can influence complex behaviors.

Breeding and gene knockout experiments reveal genetic determinants of behavior.

Single gene mutations can alter behavioral phenotypes

Are you a morning person or a night person? Some people are early risers and function best in the morning, and others have their best work hours late at night. It is possible that this big difference in the behavior of individuals could be due to differences in a single gene. This story begins with fruit flies, *Drosophila*. Fruit flies, like virtually all organisms, have daily rhythms that continue even if all external time cues are taken away. But without external time cues, these rhythms do not span exactly 24 hours, which is why they are called circadian (*circa*, “about,” + *dies*, “a day”). Investigators using chemicals to randomly mutate genes in *Drosophila* found one gene that controlled the duration, or period, of the circadian rhythms of the flies. This gene was named *per* for period, and variants of this gene caused short or long circadian periods. We now know that there are many more genes involved in circadian rhythms, and that these genes are highly conserved in organisms ranging from *Drosophila* to humans. One variant of the *per* gene in humans results in familial advanced phase sleep syndrome. The affected individuals have short circadian rhythms and tend to go to sleep and wake up earlier than others.

That single genes can influence even complex behaviors should not be surprising. Many behaviors depend on a particular signaling molecule or a particular receptor molecule, and a change in the gene for that signal or receptor could therefore dramatically change the behavior. For example, mutation in a gene for an olfactory receptor could result in the ability to sense a different odorant. Even changes in the expression pattern of a gene can alter a complex behavior. As we discussed at the beginning of [Chapter 7](#), prairie voles are highly monogamous, and both sexes give much parental care to their young. Montane voles do not form pair bonds, are promiscuous, and provide a shorter period of maternal care than prairie voles. The difference between these two species lies in the expression of the receptors for the neuropeptides vasopressin (males) and oxytocin (females): there are far fewer receptors for these neuropeptides in the brains of montane voles. We'll return to the social systems of voles in [Key Concept 52.6](#).

Knockout experiments reveal the roles of specific genes

As you may recall from [Chapter 18](#), a knockout experiment is a genetic technique in which one of an organism's genes is made inoperable ("knocked out") to see what effect its elimination has on the organism's phenotype. Knocking out genes involved in sensory pathways can have pronounced effects on behavior. One example is a gene for a specific olfactory receptor in mice.

As was discussed in [Key Concept 45.2](#), mice have two olfactory organs: the nasal olfactory epithelium common to all mammals, and a small organ in the nasal passages called the vomeronasal organ, or VNO ([Figure 52.3](#)). Catherine Dulac at Harvard University discovered that pheromone receptors were expressed in that organ. (Pheromones are signaling molecules that are released into the environment and are used for communication between individuals of the same species.) Dulac hypothesized that when sex pheromones produced by female mice bind to the receptors in the male's VNO, they stimulate mating behavior. To test this hypothesis, Dulac created a genetically engineered male mouse in which a gene for VNO receptor signaling was knocked out. Contrary to the hypothesis, the knockout males in fact did pursue and mate with females placed in their cages. However, they also pursued and tried to mate with *males* placed in their cages. Normally a male mouse reacts aggressively to a strange male, but the knockout male could not discriminate between males and females placed in his cage. Thus properly functioning VNO receptors appear to be essential not for sexual attraction, but for sex identification. You can imagine how selection working on this one gene could modify the intensity of male-male aggression and lead to changes in social behavior.

Figure 52.3 The Mouse Vomeronasal Organ Identifies Sex (A) The mouse VNO is located adjacent to the nasal passages. It contains pheromone receptors whose input travels to a specific region of the olfactory bulb (the accessory olfactory bulb). Projections from the accessory olfactory bulb go only to areas of the brain involved in sexual behavior, whereas projection from the main olfactory bulb go to many different areas of the brain (not shown). (B) In male mice, information from the VNO is crucial in identifying gender and thus a potential sexual partner.

Gene cascades can control complex behavioral phenotypes

Male courtship behavior in the fruit fly (*Drosophila*) is stereotypic, species-specific, and requires no learning—a classic fixed action pattern. When a male encounters a potential mate, he follows her, taps her body with his foreleg, extends and vibrates one wing, and licks her genitals ([Figure 52.4A](#)). The development of this complex male behavior is under the control of a single gene, called *fruitless* (*fru*), and the development of male anatomy is under the control of another gene, called *doublesex* (*dsx*). In both males and females, these two genes are part of gene expression cascades that differ in the splicing of the mRNA in the two sexes. Those splicing differences result in different *dsx* and *fru* gene products in males and females ([Figure 52.4B](#)). The female version of the Dsx protein controls the development of female anatomy, and the expression of *fru* in the male nervous system results in the organization of the neural circuitry controlling male sexual behavior.

(A) Fruit fly courtship behavior

(B) Genes responsible for sexual differentiation

Figure 52.4 The *fruitless* Gene (A) Male fruit flies display stereotypic, species-specific courtship behavior. (B) Sexual differentiation in *Drosophila* is controlled by a cascade of genes, including the *fru* gene, whose expression results in male sexual behavior.

There are two take-home lessons from this example. First, genes that control aspects of behavior, like other genes, are generally embedded in gene cascades that offer opportunities for simple genetic changes to alter the phenotype of even complex behaviors. Second, certain genes, such as *dsx* and *fru*, influence a range of other genes that contribute to complex behaviors. Modifications in any one of those genes or its expression can alter behavior. Thus even though no behavior is coded for by a single gene, alterations in single genes can influence behavior in ways that affect an animal's fitness.

52.2 recap

There are strong genetic determinants of behavior in most species. Gene manipulations such as mutations and knockouts show that a single gene can play a large role in the development and expression of a behavior. Although most behaviors are controlled by multiple genes, those genes frequently function in signaling cascades, so a single gene modification can influence even a complex behavior controlled by many genes.

learning outcomes

You should be able to:

- Give examples of a single gene influencing a behavior.
- Describe different kinds of evidence supporting the claim that single genes can influence behavior.

- Explain the evolutionary benefit of a gene expression cascade that influences behavior.
-

1. A method has recently been developed to increase the expression of oxytocin and vasopressin genes in montane voles. What difference might that treatment make in the behavior of these animals? If the expected result is not seen, what could be the reason?
2. If you interbred two individuals from separate populations that bred true for a trait that differed between the two, and all of the offspring resembled one of the parents, what would you conclude about the genetic basis for that behavior?
3. What could be an evolutionary reason for a species-specific mating behavior being controlled by a gene expression cascade, such as in *Drosophila*?

How can the genetic cascades that underlie complex behaviors be programmed to respond selectively to specific sets of stimuli? How can their expression be limited to appropriate times in an animal's life? The answers to these questions can be found by studying how behaviors develop over the life span.

52.3 Behavior Can Be Studied Developmentally

The emergence of behavior as an animal develops and matures depends on the development of the nervous system as well as on the growth and maturation of other body systems. But even with anatomical and physiological competence, specific behaviors may not be expressed. Behaviors that are adaptive at one stage in an animal's life may not be adaptive at other stages. Behaviors typical of juvenile animals, such as begging for food, may disappear and new behavior patterns of a mature individual, such as courtship displays, appear.

focus your learning

Hormones influence the development of certain behaviors and their expression at a later time. Complex behaviors can involve both genetic determinants and learning.

Hormones can determine behavioral potential and timing

Hormones can determine the development of a behavioral potential at an early age and the expression of that behavior at a later age. An excellent example of this is sexual behavior in rats ([Figure 52.5](#)). Normally, adult male and female rats exhibit different patterns of sexual behavior: females adopt a sexually receptive posture, called lordosis, in the presence of males, and males copulate with receptive females. Neither sex, however, expresses these behaviors until the animals have reached adulthood. Experiments in which newborn and adult rats were neutered (to remove the influence of sex steroids naturally produced by their gonads) and artificially treated with hormones led to the following conclusions:

(A) Sex hormone manipulations of female rats

Treatment 1	Treatment 2	Treatment 3
Spay an adult ♀ Treat with ♀ sex steroids ▼ Observe: Lordosis  Treat with testosterone ▼ Observe: No sexual behavior 	Spay a newborn ♀ Let her mature Treat with ♀ sex steroids ▼ Observe: Lordosis  Treat with testosterone ▼ Observe: No sexual behavior 	Spay a newborn ♀ and treat her with testosterone  Let her mature Treat with ♀ sex steroids ▼ Observe: No lordosis  Treat with testosterone ▼ Observe: ♂ sexual behavior in presence of receptive ♀ 

(B) Sex hormone manipulations of male rats

Treatment 1	Treatment 2	Treatment 3
Castrate an adult ♂ Treat with ♀ sex steroids ▼ Observe: No lordosis  Treat with testosterone ▼ Observe: Copulation in presence of receptive ♀ 	Castrate a newborn ♂ Let him mature Treat with ♀ sex steroids ▼ Observe: Lordosis  Treat with testosterone ▼ Observe: No sexual behavior in presence of receptive ♀ 	Castrate a newborn ♂ and treat him with testosterone  Let him mature Treat with ♀ sex steroids ▼ Observe: No lordosis  Treat with testosterone ▼ Observe: Copulation in presence of receptive ♀ 

Figure 52.5 Hormonal Control of Sexual Behavior Experimental hormone treatments of rats demonstrated that the sex steroids present during early development determine which sexual behavior patterns develop, whereas the sex steroids present in adulthood control the expression of those behavior patterns. The elimination of sex steroids during early postnatal development reveals that the default pattern of behavioral development is female.

Development of male sexual behavior requires the brain of the newborn rat be exposed to testosterone. Female sexual behavior development does not require exposure to estrogen.

Testosterone masculinizes the nervous systems of both genetic males and genetic females.

Exposure to sex steroids in adulthood is necessary for the expression of sexual behavior, but testosterone produces male sexual behavior only in adult rats whose brains were masculinized when they were newborns, and estrogen produces female sexual behavior only in adult rats whose brains were not masculinized when they were newborns.

Thus the sex steroids that are present at birth determine which pattern of behavior develops, and the sex steroids that are present in adulthood determine when that pattern is expressed.

Some behaviors can be acquired only at certain times

Responsiveness to simple releasers is sufficient for certain behaviors such as begging behavior in gull chicks, but more complex information that cannot be genetically programmed is required for other behaviors. An example is parent-offspring recognition. When animals live in close proximity to other individuals, as in a herd or a nesting colony, it is important for parent and offspring to learn each other's identity soon after birth so they will be able to find each other in a crowded situation. In many such cases, a parent-offspring bond is formed by [imprinting](#). What characterizes imprinting is that an animal learns a specific set of stimuli during a limited time called a [critical period](#), also known as a [sensitive period](#).

imprinting In animal behavior, a rapid form of learning in which an animal learns, during a brief critical period, to make a particular response (which is then maintained for life) to some object or other organism.

critical period See sensitive period.

sensitive period The life stage during which some particular type of learning must take place, or during which it occurs much more easily than at other times. Typical of song learning among birds. Also known as the critical period.

Konrad Lorenz demonstrated that young greylag geese (*Anser anser*) imprint on their parents between 12 and 16 hours after hatching. By positioning himself to be present during this critical period, Lorenz succeeded in imprinting goslings on himself. The imprinted goslings followed him around as if he were their parent ([Figure 52.6A](#)). In a subsequent experiment his assistants wore boots with different patterns on them. The goslings imprinted on the boots, and even in a situation that mixed different groups of goslings, they always sorted themselves out by following their "parental" boots.

(A) *Anser anser*

(B) *Aptenodytes forsteri*

Figure 52.6 Imprinting Helps Parents and Offspring Recognize Each Other (A) Greylag geese that imprinted on Konrad Lorenz as hatchlings followed him everywhere he went. **(B)** Imprinting allows a male emperor penguin to find his own chick among many others.

Imprinting requires only a brief exposure, but its effects are strong and long-lasting. Emperor penguins (*Aptenodytes forsteri*) reproduce during the coldest, darkest time of year in Antarctica. The parents walk up to 150 kilometers inland to form a dense colony, where the female lays her egg. She then walks back to the ocean to feed while her mate incubates the egg. By the time she returns, the chick has hatched. She then takes over its care and feeding, and the father walks back to the ocean to feed. Generally he is away so long that the mother must leave to find food to avoid starvation. Thus after being away for weeks, the father must find his chick in a crowded, milling colony of chicks, all calling for their parents ([Figure 52.6B](#)). Yet he can unerringly locate his own offspring by recognizing its call, which he imprinted on before he left to feed.

The critical or sensitive period for imprinting may be determined by a brief hormonal state. For example, if a mother goat does not nuzzle and lick her newborn within 10 minutes after its birth, she will not recognize it as her own offspring later. For goats, the sensitive period is associated with peaking levels of the hormone oxytocin in the mother's circulatory system at the time she gives birth and at the same time she is sensing the olfactory cues emanating from her newborn kid. A female goat rendered incapable of smelling before giving birth is unable to differentiate between her own kid and other kids after giving birth.

Birdsong learning involves genetics, imprinting, development, and social interactions

The study of white-crowned sparrow singing at the beginning of this chapter is a classic case of

how genetics, physiology, and experience come together in the development and expression of behavior. Genetics endows the birds with a neural template that must be matched by experience during early development. That type of learning—imprinting—is limited to a sensitive or critical period by processes of developmental physiology. Months later, the onset of sexual maturation motivates the birds to sing, initiating a second phase of learning that requires the birds to use auditory experience to develop the motor patterns required for the full expression of species-specific song ([Figure 52.7](#)). At the end of this learning phase, the song becomes permanent, or crystalized. Thus the overall process of transmission of a complex species-specific behavior necessary for reproductive success is well adapted to preserving constancy of the behavior. But variation is an important component of evolution.

Figure 52.7 Sensitive Periods for Song Learning (A) Sonogram showing the species-specific song of an adult male white-crowned sparrow (*Zonotrichia leucophrys*). (B) Song of an adult male raised in isolation (never having heard the song as a nestling). (C) Song of an adult male that heard the song as a nestling but was deafened prior to ever singing himself. Experiments showed that the bird must first acquire a song memory by hearing the song as a nestling, and must then be able to hear himself as he attempts to match his singing to that song memory.

Variation in birdsong is evident in nature. There are subtle differences between the songs of any two males, including those in neighboring territories. Regionally, white-crowned sparrows have dialects, and a bird migrating into an area that has a different dialect can adopt that song pattern. There are even observations of white-crowned sparrows singing the songs of closely related species. In an interesting laboratory experiment, white-crowned sparrows were raised in isolation but exposed to the sight and song of a male of a closely related species while recordings of white-crowned sparrow song played on speakers. When those birds matured, they sang the song of the closely related species. The ability to incorporate variation into an

individual bird's song may relate to social interactions such as fitting into a regional norm, displaying individual qualities to a potential mate, and maintaining a bond between mates.

To investigate questions about the adaptive significance of variations in the male singing behavior, it is necessary to take female choice into consideration. Sarah Woolley and Allison Doupe at the University of California, San Francisco did that with zebra finches (*Taeniopygia guttata*), a species that has become a valuable model system for studying the neurobiology of birdsong. When male zebra finches sing in isolation, their song is variable ("undirected"), almost as if they are improvising and trying out new motifs. In the presence of females, however, they sing "directed" song (directed to a female) that is less variable. Woolley and Doupe conducted experiments to see which songs female zebra finches preferred (**Investigating Life: Practice Makes Perfect**). The females preferred directed song, and if mated, they preferred the directed song of their mate. Thus the ability to incorporate variations into the species-specific song may be important to establish individuality and influence mate choice, but the nature of the singing depends on the social context.

▶ investigatinglife

Practice Makes Perfect

experiment

Original Paper: Woolley, S. C. and A. J. Doupe. 2008. Social context-induced song variation affects female behavior and gene expression. *PLoS Biology* 6(3): e62.

When male zebra finches (*Taeniopygia guttata*) sing alone, they improvise (undirected song), but when they sing in the presence of a female, they sing a stereotyped (directed) song. Woolley and Doupe asked whether the quality of the song influenced the behavior of the female.

HYPOTHESIS ▶ Female zebra finches have a preference for directed over undirected song, and can identify the song of their mates.

METHOD

1. Record males singing alone and singing in the presence of their mates.
2. Place a female in the center chamber of a three-chamber apparatus; the female should be able to move between the chambers. Play recordings of her mate's directed song in one end-chamber and of her mate's undirected song in the other end-chamber.
3. Record the amount of time the female spends in the different chambers.

Recording of mate's undirected song

Recording of mate's directed song

RESULTS

Females spent a higher percentage of time in the chamber in which their mate's directed song was played. The data show results for 17 females with means and standard deviations. The *P*-value from a paired *t*-test is <0.001 .

CONCLUSION ▶ Females can discriminate between their mate's directed and undirected songs and are more attracted to the directed song.

investigatinglife work with the data follows on next page.

work with the data

Since the experiment showed that females could distinguish between the directed and undirected songs of their mates, the next question was whether they could distinguish between the directed song of their mates and the directed song of other males. A second experiment used the same protocol as did the first one, but the two songs that were played to each female were the directed song of her mate and the directed song of an unfamiliar male. The results are shown in the table.

QUESTIONS►

1. If you hypothesized that the female's preference for her mate's directed song was a factor in pair bonding rather than just a mating stimulus, what data might you collect to test this hypothesis?
2. Plot the data as bar graphs. Show the means and standard deviations, and do a paired *t*-test to determine the significance level. Can females distinguish their mate's directed song from the directed song of an unfamiliar male?
3. What do these results suggest about the mating system of the zebra finch?
4. What hypotheses can you suggest about the function of undirected song?

A similar **work with the data** exercise may be assigned in **LaunchPad**.

The timing and expression of birdsong are under hormonal control

Both male and female songbirds hear their species-specific song as nestlings, but only the males of many species sing as adults, and most do so only in spring. Hormones underlie both the difference in song expression between male and female songbirds and the timing of song expression. When investigators injected adult female songbirds with testosterone in spring, those females sang their species-specific song just as males did. Females as well as males form a memory of their species-specific song when they are nestlings, and they have the physical capacity to sing, but under normal circumstances they lack the necessary hormonal stimulation.

How does testosterone cause a songbird to sing? Each spring an increase in circulating testosterone levels causes certain parts of the male's brain necessary for learning and developing song to grow larger. Individual neurons in those regions of the brain increase in size and grow longer extensions, and the number of neurons in those regions increases. Thus hormones can control behavior by changing brain structure as well as brain function, both developmentally and in response to environmental cues.

52.3 recap

Genetics can determine what behaviors can be learned, and hormones can determine the sensitive period when they can be learned as well as the motivational states that trigger their expression. Imprinting ensures the ability of individuals to recognize other individuals or species at a later time. Some capacity for variation of genetically determined and imprinted behaviors enables behavior to be shaped by social context.

learning outcomes

You should be able to:

- Explain how hormones can affect the timing and expression of behavior.
- Describe the evidence supporting the claim that genetics are important in bird singing behavior.
- Explain the evolutionary benefit of variability in the singing behavior of a bird species.

1. Why is female considered to be the default pathway for the development of sexual behavior in rats?
2. Explain why a songbird deafened in adulthood can sing its song, but a songbird deafened before reaching sexual maturity cannot.
3. Under what conditions might variability in a species-specific behavior be adaptive or not be adaptive?

Complex behaviors are the product of interactions of genetic, physiological, and environmental factors. Many genes are involved in shaping behavior, and therefore there are multiple opportunities for selection to favor behavioral modifications. Questions about how changes in behavior adapt animals to environmental conditions are the province of an evolution-based field called **behavioral ecology**.

behavioral ecology An evolutionary approach to the study of animal behavior that studies

how behaviors are adaptive in different environmental conditions.

52.4 Selective Pressures Shape Behavior

Most of the behaviors we have discussed so far involve interactions between individuals. The individual also interacts with its environment, and many behaviors have evolved as adaptations to the environment. Environmental conditions can be highly variable over time and space. Behavioral ecologists strive to discover the relationships between behavior and environment, with the intent of understanding the selective pressures shaping the evolution of specific behaviors. Here we offer just a few examples.

focus your learning

The evolution of behavioral responses to the environment is driven by costs and benefits.

Different types of territoriality have different costs and benefits.

The evolution of foraging behavior is driven by costs and benefits.

Animals are faced with many choices

Animal behavior is largely a sequence of choices: where and when to move, where to build a nest, what to eat, when to fight and when to flee, with whom to associate, with whom to mate. Making wrong choices reduces fitness. Behavioral ecologists seek to discover what information animals use to make behavioral choices and how that information relates to the environmental conditions that influence fitness.

Where an animal lives is referred to as its **habitat**. In most cases the habitat provides not only a protected nest site, but also food and access to mates. The environmental cues animals use to select their habitat may be quite simple. For example, seabirds select cliffs or offshore rocks for nesting, and both of those sites offer protection from predators. Animals with very specialized food requirements select habitats where those foods are abundant. The general hypothesis that guides behavioral ecologists is that the cues animals use to select habitats are reliable predictors of conditions suitable for future survival and reproduction.

habitat The particular environment in which an organism lives.

For many species, the presence of **conspecifics**—other members of the same species—can be a valuable cue. Observing conspecifics can provide animals with information about the quality of a habitat. After all, you can't argue with success. During the breeding season, European collared flycatchers (*Ficedula albicollis*) are nosy neighbors, regularly visiting the nests of conspecifics. Researchers hypothesized that this behavior allows the flycatchers to assess the quality of the habitat by seeing how well their neighbors are faring. To test this hypothesis, they created some areas with supersized broods—normally an indication of abundant food—by taking young birds from some nests and adding them to nests in another area. The next year, flycatchers preferentially settled in the areas where broods had been artificially enlarged.

conspecifics Individuals of the same species.

Behaviors have costs and benefits

A cost-benefit approach can be used to investigate the relationships between behavior, environment, and fitness. A **cost-benefit approach** assumes that an animal has only a limited amount of time and energy, and therefore cannot afford to engage in behaviors that cost more to perform than they return in benefits. A cost-benefit approach provides a framework that can be used to construct hypotheses and design experiments to investigate why behavior patterns evolve as they do.

cost-benefit approach An approach to evolutionary studies that assumes an animal has a limited amount of time and energy to devote to each of its activities, and that each activity has fitness costs as well as benefits. (See *also* tradeoff.)

The benefits of a behavior are measured in terms of the enhancement in fitness an animal accrues by performing the behavior. The cost of a behavior typically has three components:

- . **Energetic cost** is the energy the animal expends performing the behavior.
- . **Risk cost** is the increased chance of being injured or killed.
- . **Opportunity cost** is the benefit the animal forgoes by not being able to perform other behaviors at the same time.

energetic cost The difference between the energy an animal expends in performing a behavior and the energy it would have expended had it rested. (Compare with opportunity cost, risk cost.)

risk cost The increased chance of being injured or killed as a result of performing a behavior, compared to resting. (Compare with energetic cost, opportunity cost.)

opportunity cost The sum of the benefits an animal forfeits by not being able to perform some other behavior during the time when it is performing a given behavior. (Compare with energetic cost, risk cost.)

Territorial behavior carries significant costs

Territorial behavior is a good subject for cost-benefit analysis. Territoriality is aggressive behavior that actively denies other animals access to a habitat or resource. Optimal habitats and resources may be in short supply, so conspecifics have to compete for them. Many animals—usually males—defend all-purpose territories that provide a nest site, food, and access to mates. The territory holder stakes out his boundaries by engaging in aggressive interactions with neighbors, and must then patrol those boundaries constantly and respond to trespassers. These aggressive interactions usually consist of highly stereotypic, species-specific displays such as birdsong. Through territorial behavior, the male obtains the resources he needs for reproductive success, but he also pays a price.

territorial behavior Aggressive actions engaged in to defend a habitat or resource such that other animals are denied access.

Territorial displays require considerable expenditure of energy, they make a male more vulnerable to predation, and they detract from the time he has for feeding or engaging in parental behavior. Michael Moore and Catherine Marler at Arizona State University performed

an experiment to estimate the costs incurred by male Yarrow's spiny lizards (*Sceloporus jarrovi*) when defending a territory. These lizards defend territories that include the home ranges of several females. Their territorial behavior is normally most intense during September and October when circulating testosterone levels of the males are high and the females are most receptive to mating. The researchers varied the intensity of the lizards' territorial behavior by implanting testosterone capsules in some males in summer, when they are not normally highly territorial ([Figure 52.8](#)).

Figure 52.8 The Costs of Defending a Territory

Original Paper: Marler, C. A. and M. C. Moore. 1988. Evolutionary costs of aggression revealed by testosterone manipulations in free-living male lizards. *Behavioral Ecology and Sociobiology* 23: 21–26.

By using testosterone implants to increase territorial behavior, Michael Moore and Catherine Marler measured the costs to male Yarrow's spiny lizards (*Sceloporus jarrovi*) of defending a territory during the summer, when they do not normally do so.

HYPOTHESIS ▶ Yarrow's spiny lizards do not defend a territory during summer because the energetic costs of territorial behavior in that season outweigh the benefits.

METHOD

1. During the summer, when female lizards are not sexually receptive, insert testosterone capsules under the skin of some males; other males received empty capsules to serve as controls.
2. Observe the patterns of territorial behavior and the survival rate of the two groups of males.

RESULTS

CONCLUSION ▶ For these lizards, the cost of defending territories during summer significantly reduces their survival rate.

Testosterone-treated males spent more time patrolling their territories, performed more displays, and expended about one-third more energy than control males (energetic cost). They had less time to feed (opportunity cost), captured fewer insects, stored less energy, and had a higher death rate (risk costs). In summer, when females are not normally receptive, these high costs of vigorous territorial defense outweigh the reproductive benefits of territoriality. Thus natural selection has favored seasonal variation in the level of the hormone controlling territorial behavior in this species.

Animation 52.1 The Costs of Defending a Territory www.Life11e.com/a52.1

The cost-benefit approach explains the diversity of territorial behaviors seen in different species. Even if a resource is essential to an animal, if it cannot be defended economically, the animal will not engage in territorial behavior. Food is essential for all animals, but if the food is widely distributed in space or fluctuating in availability, there is no benefit to balance the high costs of trying to defend it. For example, the open ocean where seabirds feed cannot be defended. But safe nest sites on islands or rocky cliffs are in short supply, and they can be defended. The territories of seabirds may be no larger than the distance the birds can reach while sitting on their nests ([Figure 52.9A](#)).

(A) *Thalassarche melanophris*

(B) *Mirounga angustirostris*

(C) *Centrocercus urophasianus*

Figure 52.9 Animals Defend Territories of Different Sizes (A) The nesting territories of many seabirds consist of only as much space as the birds can defend without leaving the nest. **(B)** Male elephant seals fight vigorously to defend areas of beach where females haul out of the water to give birth to their pups. **(C)** Male greater sage-grouse gather at a lek in Colorado to perform displays aimed at impressing females and winning the opportunity to mate.

In some cases the resource that is defended is the female herself. Elephant seals spend most of their lives at sea, but females come to land at traditional beach sites to give birth to their pups. Male elephant seals arrive at these sites ahead of time and stake out territories through vigorous fighting ([Figure 52.9B](#)). When the females arrive on the beaches, they have to enter the territories of the males. As long as the male territory holder can fend off challengers, he will be able to mate with all the females using his piece of the beach.

One unusual form of male territorial behavior arises in situations in which neither food, nest sites, nor females are defended. A [lek](#) is an area where males gather for the purpose of engaging in intense displays of their territorial prowess aimed at impressing females and winning the opportunity to mate. Even though space is not limited, each male defends a small piece of real estate on which he performs a display ([Figure 52.9C](#)). Those territories closest to

the center of the lek are the prime sites, and males compete intensely for those locations. The females visit the lek, observe the males, and generally mate with the males holding the prime sites. The benefit of this system to the female is that she is inseminated by a successful competitor, and therefore her offspring will carry the genes that contributed to his success. This is another example of sexual selection (see [Key Concept 20.2](#)). The costs of lekking to males are high, as they engage in continuous, intense territorial behavior that precludes eating, drinking, and sleeping until they are displaced. The benefit is the chance to maximize their fitness by mating with many females.

lek A display ground within which male animals compete for and defend small display areas as a means of demonstrating their territorial prowess and winning opportunities to mate.

Foraging behavior has costs and benefits

Searching for food (foraging) involves many decisions: how much time to spend in each location, what is edible, and which potential foods should be eaten and which should be ignored. A cost-benefit approach to feeding behavior has resulted in an [optimal foraging theory](#), which aims at identifying the fitness value of feeding choices. The primary benefit of foraging is nutrition: energy, minerals, and vitamins (see [Key Concept 50.1](#)). The costs of foraging are similar to those of other behaviors: energy expended, time lost from other activities that could enhance fitness, and the risk of increased exposure to predators.

optimal foraging theory The application of a cost–benefit approach to feeding behavior to identify the fitness value of feeding choices.

Animals frequently make choices among food items that may differ not only in terms of energy content, but also abundance or ease of acquisition and processing. Optimal foraging theory predicts that in such situations, animals will make choices that will maximize the rate at which they obtain energy. The more rapidly a foraging animal satisfies its energetic requirements, the lower the opportunity costs and risk costs of foraging.

The energy maximization hypothesis considers food items in terms of the energy they provide, but animals have nutrient requirements in addition to energy that can play a role in shaping their foraging behavior. Essential minerals, for example, are in short supply in some animals' diets, and those animals may incur large energetic costs and risks to obtain them ([Figure 52.10](#)). Some foods may also be sought for their medicinal value. Chimpanzees, for example, have been observed eating the pith of the plant *Vernonia amygdalina*. The pith contains small quantities of a secondary metabolite (vernionioside B1) that is toxic to chimps at high concentrations, but at low concentrations can kill their intestinal parasites. Chimps that consume this plant material have fewer parasites.

 Animation 52.2 Foraging Behavior www.Life11e.com/a52.2

52.4 recap

Many behaviors are shaped by environmental conditions that influence the decisions animals must make. Decisions can result in benefits that increase reproductive fitness, but they also involve costs, including energetic costs, opportunity costs, and risk costs. Cost-benefit analysis can be applied to territorial and foraging behaviors.

learning outcomes

You should be able to:

- Describe how a cost-benefit approach is applied to investigating animal behavior.
- Describe different types of territorial behaviors and the cost and benefit factors that shape their evolution.

- Explain why aggressive territorial behavior is associated with some essential resources, but not others.
 - Foraging involves trade-offs between nutrients acquired and the costs of energy required, opportunity loss, and risk.
-

1. Male redwing blackbirds prefer to build nests in marshes, but they feed in upland meadows. What costs and benefits most likely shaped these behaviors?
2. Cichlid fish have dominant males that have colorful markings and defend territories. There are also nondominant males that are plain and do not defend territories but occasionally dash in when a female is spawning to try to fertilize some of her eggs. What are the costs and benefits of these two male phenotypes?
3. Elephant seals defend a piece of beach as a mating territory, whereas prairie-chickens defend small pieces of grassland as a mating territory. Male elephant seals are much larger than the females and viciously fight with one another over their territories. Male prairie-chickens are not much larger than females; they have elaborate displays, and they don't fight viciously with neighboring males. What selective pressures have shaped the behaviors of these two different kinds of animals that defend mating territories?
4. Consider a species that has a choice of two potential sources of food. One is calorie-rich, but is dispersed in a sparse environment. The other is calorie-poor but occurs in dense patches in a protected environment. Which types of selective pressures would likely shape the food preference of this species?

Behavioral ecologists are interested in understanding how the natural environment influences the fitness value of behavioral choices—the ultimate causes of those behaviors, in Tinbergen's terms. Other behavioral biologists focus on the physiological mechanisms that underlie the proximate causes of behavior.

52.5 Behavior Can Be Studied Mechanistically

Control of behavior involves the nervous and endocrine systems. Execution of behavior involves the musculoskeletal system as well as other effector mechanisms, such as those that produce secretions, color changes, electrical impulses, sound, and even light. We have already considered many of the physiological systems that are involved in these processes, including hormones, reproductive systems, nervous systems, sensory systems, and feeding mechanisms. The field of behavioral physiology, which encompasses aspects of all of these systems, is enormous, so here we will dig deeper into just three different phenomena studied by behavioral physiologists: the timing of behavior, navigation, and communication.

focus your learning

Animals have genetically determined daily and annual rhythms that enable them to anticipate future conditions.

Animals can navigate using landmarks or time and direction information, and some use true bicoordinate navigation.

Animals communicate using light, sound, mechanical, and chemical signals.

Biological rhythms coordinate behavior with environmental cycles

Earth turns on its axis once every 24 hours, generating daily cycles of light and dark, temperature, humidity, and tides. In addition, Earth is tilted on its axis, so the light-dark cycle changes as Earth revolves around the sun. These daily and seasonal cycles profoundly influence the physiology and behavior of animals. Animals tend to be active either during the day (diurnal) or at night (nocturnal) and have sensory capabilities appropriate to this distinction. Therefore it is adaptive to organize behavior on a cycle that corresponds with the environmental cycle of light and dark. Similarly, a behavior that is adaptive at one time of year (such as midsummer) may not be adaptive at another time (midwinter). Thus it is important for animals to organize their behavior with respect to time of the day or year and to be able to anticipate those times.

CIRCADIAN RHYTHMS Experimental animals kept under constant conditions with no daily time cues such as light and dark, temperature cycles, or episodic availability of food and water still have daily cycles of activities such as locomotor activity, sleeping, eating, drinking, learning, and just about anything else that can be measured. The persistence of these daily cycles in the absence of environmental time cues suggests that animals have an internal clock. As we mentioned above, because these daily cycles are not exactly 24 hours long, they are known as [circadian rhythms](#).

circadian rhythm (sir kade' ee an) [L. *circa*: approximately + *dies*: day] A rhythm of growth or activity that recurs about every 24 hours.

Biological rhythm can be viewed as a series of cycles, and the length of one of those cycles is the period of the rhythm. Any point in the cycle is a phase of that cycle. When two rhythms

completely match, they are in phase, and if a rhythm is shifted (as in the resetting of a clock), it is phase-advanced or phase-delayed. Because the period of a circadian rhythm is not exactly 24 hours, it must be phase-advanced or phase-delayed each day to remain in phase with the daily cycle of the environment. In other words, the rhythm has to be **entrained** to the environmental cycle of light and dark.

entrain To advance or delay an organism's circadian clock each day so that it is in phase with the light-dark cycle of the organism's environment.

The circadian rhythm of an animal held under constant conditions will run according to its natural period—it will be **free-running**. If the period is less than 24 hours, the animal will begin its activity a little earlier each day (**Focus: Key Figure 52.11**). The period of the free-running circadian rhythm is under genetic control. Different species may have different average periods, and within a species, mutations can lead to different period lengths.

free-running A descriptor of an endogenous rhythm that is not entrained by an environmental cue.

focus: key figure

On a cycle of 12 hours light/12 hours dark, the mouse is mostly active in the dark and has a rest-activity cycle of 24 hours.

In constant dark, the mouse still expresses a daily cycle of rest and activity, but the period of the cycle is less than 24 hours. As a result, the mouse starts its activity and ends its activity earlier each day.

If the mouse is given 20 minutes of light at 24-hour intervals, its rest-activity cycle becomes entrained to that 24-hour period.

Figure 52.11 Circadian Rhythms Are Entrained by Environmental Cues The activity-rest cycle of a laboratory mouse (a nocturnal animal) responds to the light-dark cycle under which it is kept. The gray bars indicate times when the mouse is running on an activity wheel. Two days of activity are represented on each horizontal line. Thus, day 1 is 0-24 and day 2 is 24-48. Then on the next line day 2 is replotted

as 0-24 and day 3 is 24-48, and so on. This double plotting is merely to make the pattern easier to see.

Q: In going from the last activity tracing in the second panel to the light-pulse experiment in the third panel, do this transition and its effects on the circadian clock seem more similar to what you experience if you are recovering from jet lag after traveling from San Francisco to New York, or in the opposite direction?

Animation 52.3 **Circadian Rhythms** www.Life11e.com/a52.3

Under natural conditions, environmental time cues, such as the onset of light or dark, entrain the free-running rhythm to the light-dark cycle of the environment. In the laboratory it is possible to entrain the circadian rhythms of free-running animals with short pulses of light or dark administered every 24 hours (see the bottom panel of [Figure 52.11](#)).

In mammals, the master circadian “clock” consists of two clusters of neurons just above the optic chiasm (the area of the brain where the optic nerves come together). These structures are called the **suprachiasmatic nuclei (SCN)**. If they are destroyed, the animal becomes arrhythmic (loses its circadian rhythm) and is just as likely to eat, drink, sleep, or wake at any time of day.

suprachiasmatic nuclei (SCN) In mammals, two clusters of neurons just above the optic chiasm that act as the master circadian clock.

A notable study by Martin Ralph and his colleagues, then at the University of Virginia, demonstrated that the SCN is the source of circadian rhythms. When the SCNs of adult hamsters with typical 24-hour rhythms were destroyed, the animals became arrhythmic. After several weeks of this arrhythmic behavior, the researchers transplanted SCN tissue from hamster fetuses bred for an atypical (mutant) short-day rhythmicity into the original hamsters' brains. The experiment produced two remarkable results ([Figure 52.12](#)). First, circadian rhythms were restored by the transplanted SCN tissue, demonstrating that the SCN is sufficient to generate circadian rhythms—a unique case of a behavior being restored by a neural transplant. Second, the restored circadian rhythms had the period length of the *donor* strain, demonstrating that the specific phenotype of the behavior was a property of the donor neural tissue, and thus wholly generated by the SCN.

Figure 52.12 The Brain Clock Can Be Transplanted In this experiment, the activity rhythm of a wild-type (i.e., genetically typical) hamster was measured; this animal had a circadian period of 24.5 hours (top of bar). After its SCN was removed (lesioned), the hamster became arrhythmic. SCN tissue from a fetal “short-day” hamster (a mutant strain with a 19-hour circadian period) was then transplanted into the region where the lesion was made in the wild-type hamster. The transplanted tissues restored circadian rhythm in the lesioned hamster, but the restored rhythm had the period of the donor animal.

The molecular mechanism of the circadian clock involves negative feedback loops. Although there are several genes involved, including the *per* gene discussed in [Key Concept 52.2](#), we can generalize about the mechanism by saying that when certain “clock genes” are expressed in SCN cells, the mRNA enters the cytoplasm, where it is translated. The resulting proteins combine, and the dimer returns to the nucleus as a transcription factor that shuts off the

expression of the clock genes until the transcription factor is degraded. The period of this cycle is about a day. These findings show that it is possible to understand circadian rhythms of behavior at all levels, from the molecular rhythm generators to the environmental stimuli that entrain them to the daily cycle of light and dark.

CIRCANNUAL RHYTHMS Seasonal changes in the environment present challenges to many species. Most animals reproduce most successfully if they time their reproductive behavior to coincide with the most favorable time of year for the survival of their offspring. Many species require considerable advance preparation for reproduction. Migratory animals must arrive on their breeding grounds at the right time, and animals that have specialized structures used in mating displays, such as the antlers of deer, moose, and caribou, must grow these structures before the breeding season arrives.

For many species, a change in day length—the ***photoperiod**—is a reliable indicator of seasonal changes to come. For others, however, change in day length is not a reliable seasonal cue. Hibernators, for example, spend long months in dark burrows underground but must be physiologically prepared to breed almost as soon as they emerge in the spring. A bird overwintering near the equator cannot use changes in photoperiod as a cue to time its migration to its temperate-zone breeding grounds. When held under constant laboratory conditions, such animals show endogenous circannual rhythms that keep track of the time of year. Unlike for circadian rhythms, the neural basis for circannual rhythms is unknown.

Animals must find their way around their environment

To locate suitable habitats, find food and mates, and avoid predators and bad weather, an animal needs to be able to find its way around its environment. Within its local habitat, an animal can orient to landmarks. But what if its destination is a considerable distance away?

PILOTING: ORIENTATION BY LANDMARKS Most animals find their way by knowing and remembering the structure of their environment, a form of navigation called **piloting**. Gray whales, for example, migrate seasonally between the Bering Sea and the coastal lagoons of Mexico (**Figure 52.13**). They find their way in part by following the western coast of North America. The rules are simple: keep the land on your right when traveling north and on your left when traveling south. Coastlines, mountain chains, rivers, water currents, and wind patterns can all serve as piloting cues for animals. But many remarkable cases of long-distance orientation and movement cannot be explained by piloting.

piloting A form of navigation in which an animal finds its way by remembering landmarks in its environment.

Figure 52.13 Piloting Gray whales (*Eschrichtius robustus*) migrate south in winter from the Bering Sea to the coast of Baja California by piloting, in part by following the western coast of North America.

 Activity 52.1 Homing Simulation www.Life11e.com/ac52.1

HOMING: RETURN TO A SPECIFIC LOCATION The ability to return to a nest site, burrow, or other specific location is called **homing**. Homing can be accomplished by piloting in a known environment, but some animals that travel long distances through unfamiliar territory perform much more sophisticated homing. The ability of pigeons to return to their home loft even after being transported to remote sites is well known. How do they find their way home? Experiments have shown that pigeons use the sun as a compass, but they can still find their way home when the sun is not visible. Other experiments have shown that pigeons equipped with frosted contact lenses can find their way home, suggesting that visual cues are not essential. Most amazing has been the demonstration that pigeons can detect Earth's magnetic field and orient to it much as a human orients with a compass. Taken together, the studies of homing by pigeons suggest that they can use multiple, redundant sources of directional information and can switch among those sources depending on the circumstances.

homing In animal navigation, the ability to return to a nest site, burrow, or other specific location.

MIGRATION: NAVIGATION OVER GREAT DISTANCES For as long as humans have inhabited high latitudes, they have been aware that entire populations of animals, especially birds, disappear and reappear seasonally. Not until the early nineteenth century, however, were patterns of migration traced by marking individual birds with identification bands around their legs. Only when individuals could be unmistakably identified was it possible to show that the same birds and their offspring returned to the same breeding grounds year after year, and that these same birds could be found during the nonbreeding season at locations hundreds or even thousands of kilometers from their breeding grounds.

Many homing and migrating species take direct routes to their destinations through environments they have never experienced because they use mechanisms of navigation other than piloting. Humans use two major forms of navigation:

- . *Distance-direction navigation* requires knowing in what direction and how far away the destination is. With a compass to determine direction and a means of measuring distance, humans navigate.
- . *Bicoordinate navigation*, also known as true navigation, requires knowing the latitude and longitude (the map coordinates) of both the current position and the destination, as well as a compass to determine direction.

Many animals seem to have a “compass sense” that allows them to use environmental cues to determine direction, and some seem to have a “map sens” that allows them to determine their position.

The behavior of some animals suggests that they are capable of bicoordinate navigation. Gray-headed albatrosses (*Thalassarche chrysostoma*), for example, breed on oceanic islands in the Southern Hemisphere. When a young albatross leaves its parents’ nest, it flies widely over the southern oceans for 8-9 years. After those wandering years, it reaches reproductive maturity and flies back to the island where it was raised, where it mates and builds a nest ([Figure 52.14](#)). How can the bird find a tiny island in an enormous ocean after years of wandering? We don’t know the answer, but the albatross provides strong circumstantial evidence that an animal can be capable of bicoordinate navigation, as were sailors before the days of global positioning satellites.

(B) *Thalassarche chrysostoma*

52.14 Coming Home (A) Gray-headed albatrosses are born on islands in the subantarctic oceans. Young birds roam widely over the southern oceans for 8-9 years. **(B)** Once they reach maturity, the birds return to the island where they were hatched to mate and raise their own young.

The ability to locate a position by calculating the angles between celestial objects such as the sun and stars and the horizon at specific times of day is called celestial navigation. During the day, the sun can serve as a compass if you know what time it is, and animals can use their circadian clocks for that information. This capacity has been demonstrated by “clock-shifting” experiments such as the one shown in [Figure 52.15](#). Similar experiments have shown that many animal species can orient by means of a time-compensated solar compass.

Figure 52.15 A Time-Compensated Solar Compass

Original Paper: Kramer, G. 1952. Experiments on bird orientation. *Ibis* 94: 265–285.

Experiments show that pigeons use the sun to establish directions for navigation and finding food. “Clock-shifting” experiments demonstrate that the birds’ circadian clocks factor into their ability to judge direction correctly based on the sun’s position.

HYPOTHESIS ▶ Pigeons determine compass direction from the position of the sun with respect to their internal circadian clocks.

METHOD

1. Place a pigeon in a circular cage from which it can see the sun and sky, but not the horizon or any other visual cue.
2. Surround the cage with multiple food bins but place food only in the southernmost bin, thus training the bird to look for food in the south. (Rotating the cage but always placing the food in the southernmost bin confirms that the bird is navigating to find south.)
3. Place the trained pigeon in a room with a controlled light cycle for 2 weeks. Turn the lights on at midnight and off at noon to phase-advance its circadian rhythm by 6 hours (i.e., 6 A.M. feels like noon to the bird).
4. Return the pigeon to the circular cage under natural light and observe its food-seeking behavior.

RESULTS

A 6-hour shift in the circadian clock results in a 90-degree error in the pigeon's orientation.

CONCLUSION ▶ Pigeons have the ability to determine direction using time of day and the position of the sun as a compass.

Many animals are normally nocturnal; in addition, many diurnal bird species migrate at night and thus cannot use the sun to determine direction. The stars offer two sources of information about direction: moving constellations and a fixed point. The positions of constellations (like that of the sun) change because Earth is rotating. With star map and a clock, direction can be determined using any constellation. But one point that does not change position during the night is the point directly over the axis on which Earth turns. In the Northern Hemisphere, the star Polaris—the “North Star”—lies in that region of the sky and reliably indicates north.

Stephen Emlen at Cornell University showed that birds can learn to use the stars for orientation. As the time of year approaches when young birds would normally migrate to their winter range, young captive birds become more active and orient their activity in the direction they would fly. How do they know that direction? If these birds are raised in a planetarium with a natural star pattern, but one that does not rotate, the birds do not learn to orient, and their premigratory activity is random. However, if the planetarium sky rotates, and even if it rotates around a different point than the North Star, the birds orient their premigratory activity as if the fixed point in the sky were north.

Animals use multiple modalities to communicate

As individual animals interact, they exchange information; therefore animal behaviors can evolve into systems of information exchange, or **communication**. The behaviors of individuals may become elaborated into communication signals, but only if the transmission of information benefits both the sender and the receiver. To understand why these conditions must be met, consider male courtship displays, which can be quite bizarre, time- and energy-consuming, and involve risk. Nevertheless, natural selection will favor them if they increase the males' probability of mating and passing on their genes. The displays can produce that result if they convey information to the females (the receivers) about the qualities of the males as potential fathers.

communication A signal from one organism (or cell) that alters the functioning or behavior of another organism (or cell).

Animals communicate using a variety of sensory modalities that vary in the nature of the signal produced, the specificity of the information conveyed, the speed and persistence of the signal, and its suitability in different environments. Behavioral physiologists interested in communication must take into consideration the sensory and motor characteristics of their study animals, the physics of the communication modalities they use, and the environment in which the communication takes place.

CHEMICAL SIGNALS Because of the diversity of their molecular structures, **pheromones** can communicate very specific, information-rich messages (see [Key Concept 45.2](#)). Pheromones are effective day and night, and they can cover a broad range of transmission distances. Pheromones used in different types of communication vary in their volatility (ease of vaporization) and diffusibility; these chemical properties are functions of the nature and size of the pheromone molecule. Pheromones that act as alarm signals, for example, are highly volatile and diffusible, so their message spreads rapidly but disappears rapidly. Territory-marking and trail-marking pheromones have low volatility and diffusibility and stay effective for a long time, so they can convey directional information. Sex pheromones, such as that of the gypsy moth (see [Figure 45.4](#)), are intermediate in these properties, so they can spread a long distance but do not disappear rapidly.

pheromone (feer' o mone) [Gk. *pheros*: carry + *hormon*: excite, arouse] A chemical substance used in communication between organisms of the same species.

Pheromones are an effective way to exchange species-specific information, and because the recipient must have the proper receptor molecule to detect the pheromone, it is not a signal that is easily intercepted by predators. Pheromonal signals cannot be changed rapidly, but they can convey static, complex information. Mammals that mark their territories with pheromones reveal a great deal of information about themselves: species, individual identity, reproductive status, size (indicated by the height of the marking), and how recently the animal has been in the area (indicated by the strength of the scent).

VISUAL SIGNALS Visual signals offer the advantage of rapid delivery of information over considerable distances (depending on the environment and the visual acuity of the receiver); they also convey the exact position of the signaler. Signal content can be enhanced by movements (as in a courtship display) or by different postures. Effective visual signals, however, require sufficient light, and the receiver must be looking at the signaler. Thus visual communication is not particularly useful at night or in environments that lack light, such as caves and ocean depths. Some species have overcome this constraint with light-emitting mechanisms. Fireflies, for example, use an enzymatic mechanism to create flashes of light. By emitting flashes in species-specific patterns, fireflies advertise for mates at night.

Another drawback of visual signals is that they can be intercepted by other species. There are predatory firefly species, for example, that mimic the flash pattern of females of other species. A male that approaches the mimicking “female” becomes a meal rather than a mate. Thus deception can be part of animal communication systems, just as it is part of human communication.

ACOUSTIC SIGNALS Sound cannot convey complex information as rapidly as visual signals can. But acoustic signals, unlike visual signals, can be used at night and in dark environments. They are not hindered by objects that would interfere with visual signals, so they can be transmitted in complex environments such as forests. They are often better than visual signals at getting the attention of a receiver because the receiver does not have to be looking at the signaler for the message to be received. Sounds are also useful for communicating over long distances. Even though the intensity of a sound decreases with distance from the source, loud sounds can transmit information over much longer distances than visual signals can. The complex songs of humpback whales, when produced at ocean depths of about 1,000 meters, can be heard hundreds of kilometers away, allowing these whales to locate one another across vast expanses of ocean. Humpback whale populations that feed during the summer in the north Pacific Ocean migrate thousands of kilometers to winter breeding areas in either the eastern Pacific Ocean, the mid-Pacific Ocean (Hawaii), or the western Pacific Ocean (see [Figure 54.4](#)). Long-distance communication among individuals spread over such enormous expanses of open ocean is important if they are to congregate in rather limited breeding areas at the same time of year.

The information content of acoustic signals can be increased by varying their frequency, as you can see in the sonograms of the species-specific song of white-crowned sparrows shown in [Figure 52.7](#), and as you practice in your own speech. However, acoustic signals place the signaler at risk for detection by predators. This danger can be minimized by adjustments of frequency and signal structure that decrease the directional information the receiver can extract from the signal. Alarm calls tend to be pure tones (a single frequency) without much temporal structure (starts and stops). It is very difficult to localize such calls. By contrast, territorial calls tend to cover a broad frequency range and have temporal structure. These calls are easy to localize. The frequencies and structures of acoustic signals are also adapted to specific habitats. Different vegetation types, for example, have different sound-absorbing properties: pure tones at

lower frequencies carry better in forests, and more complex calls at higher frequencies carry well in open habitats.

MECHANOSENSORY SIGNALS Animals in close contact with one another can communicate by touch. A classic case of mechanosensory communication is the dance of honey bees (*Apis* spp.), first described by Karl von Frisch. Honey bees have a spectacular ability to navigate and can accurately communicate the location of food sources as far away as 10 kilometers. When a forager bee finds food, she returns to the hive and communicates her discovery to her hivemates by performing a vigorous [waggle dance](#) in the dark hive on the vertical surface of the honeycomb. Other bees follow the dancer and receive her message.

waggle dance A behavior of honeybees that communicates the direction and distance to a food source or a location for a new colony.
--

The waggle dance conveys information about both the distance and the direction of the food source. The dancing bee repeatedly traces out a figure-eight pattern as she runs on the honeycomb. She alternates half-circles to the left and right with vigorous wagging of her abdomen in the short, straight run between turns ([Figure 52.16](#)). Bees use the sun as their compass, and the angle of the straight run indicates the direction of the food source relative to the position of the sun projected down to the horizon. Even under cloudy conditions, the forager can provide directions to the food source because she can see polarized light. The bee's circadian clock allows the dancer to adjust her dance to take into account the sun's movement during her return flight. The clocks of the recruits enable them to adjust their flight direction to accommodate the sun's movement.

Figure 52.16 The Honey Bee Waggle Dance (A) A honey bee (*Apis mellifera*) runs straight up on the vertical surface of the honeycomb in the dark hive while wagging her abdomen to tell her hivemates that there is a food source in the direction of the sun. (B) When her waggle runs are at an angle from the vertical, the other bees know that the same angle separates the direction of the food source from the direction of the sun.

 Activity 52.2 Honey Bee Dance Communication www.Life11e.com/ac52.2

The distance to the food source is communicated by the duration of the waggle portion of the dance. The farther away the food source is, the longer the duration of each waggle run. When food is close to the hive, the waggle portion of the dance becomes so short that it appeared to von Frisch that it was a different dance, which he called a round dance. Thus the honey bee has a dance language that communicates both the distance and the direction to a food source.

When challenged to prove that the bees were not simply using an odor trail to find the indicated food source, von Frisch responded with a very common sense observation. Bees returning from a new food source fly around barriers such as buildings, but the recruits going out to the food source fly over the barriers in a “beeline,” which would be impossible if they were following an odor trail. Careful observation is still one of the best tools for studying behavior.

COMMUNICATION IN MULTIPLE SENSORY MODALITIES Avoiding ambiguity is a high priority in any signaling system. Signal specificity is enhanced if multiple sensory modalities are

used. Courtship behavior in fruit flies, for example, involves visual, tactile, chemical, and acoustic signals (see [Figure 52.4A](#)). The male fruit fly orients toward the female's line of vision (visual signal) and taps her body with his foreleg (tactile signal). Upon detecting pheromones in her cuticle (chemical signal), the male begins to vibrate one wing, producing a species-specific courtship song (acoustic signal). The male then extends his mouthparts to taste the female's genitalia (chemical and tactile signals); if she is receptive, he initiates copulation. If at any point sensory feedback indicates to either the male or the female that their pairing is inappropriate, the courtship abruptly ends.

52.5 recap

Biological rhythms allow an animal to anticipate changes in its environment. In mammals, a circadian clock located in the suprachiasmatic nuclei generates a rhythm that is entrainable by environmental information. The navigational abilities of animals range from simple piloting by landmarks to distance-direction and bicoordinate navigation. Behaviors may evolve into communication signals if the transmission of information benefits both the sender and the receiver.

learning outcomes

You should be able to:

- Describe characteristics of circadian rhythms.
- Explain the concept of a time-compensated solar compass.
- Describe the different forms of animal communication and their advantages and disadvantages.
- Evaluate the effectiveness of various forms of animal communication in specific circumstances.

1. What is a free-running circadian rhythm, and how is it entrained by light to the 24-hour day?
2. Why is it important for honey bees to have a time-compensated solar compass, and how does that mechanism influence the waggle dance?
3. Which forms of communication are most efficient for inter-individual communication and for broader population-level communication? Explain your answer.

When behaviors involve interactions between multiple individuals, we have to consider how natural selection operates on all of the interacting parties, whether they are sending signals or receiving them. This concern becomes particularly relevant in the case of social behaviors.

***connect the concepts** Photoperiodism is also a common phenomenon in plants that have to anticipate seasonal changes, and many do so by being sensitive to the length of the night. See [Key Concept 38.2](#).

52.6 Social Interactions Shape the Evolution of Behavior

Our discussion of behavior has focused mostly on behavior in individual animals. We've covered, for example, fixed action patterns, deprivation experiments, genetic determinants, development, and physiological mechanisms. Yet most behavior takes place in a social context. Social behavior and its evolution became a field of study in its own right in 1975, with the publication of E. O. Wilson's landmark book *Sociobiology*.

focus your learning

Reproductive success of genetically related individuals contributes to an animal's inclusive fitness.

Eusocial systems include nonreproductive members.

The evolution of social behavior can be analyzed using a cost-benefit approach.

Mating, parenting, group behaviors such as migration, and group living such as in animal colonies all involve interactions among individuals, and selection operates on all participants in these interactions.

Mating systems evolve to maximize fitness

We begin consideration of this enormous field of social behavior with mating behavior involving a single male and a single female. Because natural selection is always operating to maximize the reproductive success of both the male and the female of the species, an amazing array of mating systems has evolved.

MONOGAMY AND PROMISCUITY

At the start of [Chapter 7](#) you learned about the mating behavior of two species of voles. Prairie voles (*Microtus ochrogaster*) are monogamous, forming strong pair bonds that can last for life, and both parents participate in rearing the young. In contrast, montane voles (*M. montanus*) are promiscuous: males mate with many females, and the young are raised by the female alone. Behavioral physiologists have explained the proximate mechanisms behind these stark behavioral differences in terms of the release of neurohormones and the distribution of the receptors for those hormones in the brains of the two species. The ultimate question—and the one asked here—is why two such different mating systems evolved in two species that are so closely related.

We begin with the premise that there is an asymmetry in the contributions of male and female animals to their offspring at the time of fertilization. Females produce a limited number of eggs, and each egg is generously stocked with resources. Males produce an almost infinite number of sperm, which contain next to no resources. So the energetic and opportunity costs of reproduction are greater for the female than for the male. In mammals this asymmetry increases throughout gestation as the female bears most of the costs. By the time of birth or hatching, the female's investment in the young is much greater than the male's investment, and the main way for the female to maximize her fitness is to make sure her young are healthy and survive to pass on her genes.

The male has different options for maximizing his fitness. He can simply move on after

inseminating the female and seek additional mates as a means of maximizing his reproductive success—as in the case of the montane vole. Or he can stay with the female he inseminated, protect her, and help care for their young—as in the case of the prairie vole. Which strategy maximizes male fitness in these species depends on a number of factors that are influenced by the environment, such as the likelihood that a female and her offspring will survive without a male's help, and a male's likelihood of finding another fertile female. Thus sociobiologists seek to quantify these factors in nature as a means of explaining observed differences in mating systems.

POLYGyny

Mating systems in which a male has more than one mate generally involve a male that manages to sequester a group of females from other males. The **polygynous** male increases his fitness by increasing the number of females in his group. As you saw in [Key Concept 52.4](#), male elephant seals accomplish this by protecting an area of beach where females give birth. Male baboons do so by herding females. Male red-winged blackbirds may acquire more than one mate by defending high-quality nesting territories where females prefer to build their nests. Since sex ratios in all these species are close to 50:50, a large differential in male fitness is established, with some males having high reproductive success while many males have none. Thus selection favors males that are successful in competing with other males to obtain and protect access to many females. In general, bigger, stronger males are the winners, and sexual dimorphism in body size evolves. The elephant seal is an extreme example: males may weigh more than three times as much as females. When species with polygynous mating systems are compared, there is a strong correlation between the number of females a male controls and the degree of sexual dimorphism.

polygyny Mating system in which one male mates with multiple females. (Contrast with polyandry.)

Why do females participate in these polygynous mating systems? Why doesn't a female seek out a nice, kind, noncompetitive male? In some cases, such as the female elephant seal, she has no choice. If a female red-winged blackbird wants to nest in an optimal territory, she will have to share the attentions of the territory owner with other females. Even if the female has a choice of mates, she is likely to maximize her fitness by mating with a male that is strong and dominant enough to control a number of females. Why? If her mate is a dominant male, her male offspring are likely to have their father's traits, become dominant males, and give her more grandchildren. Nonrandom mate choice by females based on male characteristics produces ***sexual selection**. An extreme result of sexual selection is the lek mating system (see [Figure 52.9C](#)), in which the *only* thing a male offers a female is the display of his dominance over other males.

POLYANDRY

Mating systems in which one female mates with multiple males are relatively rare, but **polyandry** is seen in some birds and a few mammal species in which paternal care for the young can have a large effect on fitness. An example of a polyandrous species is the golden lion tamarin (*Leontopithecus rosalia*), a primate native to Brazil's tropical rainforests ([Figure 52.17](#)). Tamarins are small—adults weigh less than 1 kilogram and face high predation pressure. Females usually give birth to twins, and newborns constitute a higher percentage of maternal weight than is typical of other primates. The young also grow more rapidly than other primates, so nursing costs are high. For all these reasons, young tamarins cared for by their mother alone are unlikely to survive.

polyandry Mating system in which one female mates with multiple males. (Contrast with polygyny.)

Figure 52.17 Polyandry in a Small Primate The endangered golden lion tamarins of Brazil are small primates whose unique life history has given rise to polyandry in some groups, with males playing a major role in rearing the young.

Leontopithecus rosalia

What can a male tamarin do to help guarantee his reproductive success? Watching out for predators is one obvious contribution; gathering food for the female and her young is another. Like other primate parents, tamarins carry their young most of the time, but most other primates have single offspring. When tamarin mothers are carrying twins, they spend 92 percent of the time resting, compared with 58 percent of the time when they are not carrying young. Resting is not compatible with foraging and filling the mother's high energy requirements. When a male is present, however, he carries the young about one-third of the time, so the mother has much more time for foraging and feeding.

If one male tamarin is helpful in protecting and raising young, then two should be even more helpful. Some females can attract a second mate by being sexually receptive to him. Neither male can be sure that any eventual offspring are his, so it is in the best interest of both to help in their rearing. Of the tamarin families observed in field studies, only 22 percent had one male and one female, whereas 61 percent had multiple males and one female.

Fitness can include more than your own offspring

As humans, we readily understand the concept of extended family—brothers, sisters, aunts, uncles, nieces, nephews. Extended families are a common form of social organization in other species as well, and members of these families may cooperate in territory defense, predator avoidance, foraging, and rearing of young. If behavior is favored when it increases the fitness of the individual performing it, then how can we explain the evolution of social behaviors that do not lead to the performer having more offspring and that may even appear to be **altruistic**—benefiting another individual at a cost to the performer?

altruistic Pertaining to behavior that benefits other individuals at a cost to the individual who performs it.

An individual's fitness is increased by having offspring because those offspring carry the parent's genes into the next generation. Fitness gained by producing offspring is referred to as

direct fitness. However, an individual's genes are carried into the next generation by more than his or her own offspring. In diploid organisms, two offspring of the same parents share, on average, 50 percent of the same alleles, and an individual is likely to share 25 percent of its alleles with its siblings' offspring (nieces or nephews). Therefore, by helping parents and other relatives raise their offspring, an individual increases the transmission of those shared alleles to the next generation. **Inclusive fitness** is the individual's direct fitness plus its **indirect fitness:** the reproductive success of the individual's relatives, to the extent that those relatives share the individual's alleles.

direct fitness That component of fitness resulting from an organism producing its own offspring. (Contrast with inclusive fitness.)

inclusive fitness The sum of an individual's genetic contribution to subsequent generations both via production of its own offspring and via its influence on the survival of relatives who are not direct descendants. (See *also* indirect fitness, kin selection. Contrast with direct fitness.)

indirect fitness The component of inclusive fitness due to the reproductive success of related individuals times the percentage of shared genes between those individuals (e.g., 50% for a sibling).

The maximization of inclusive fitness is the mechanism driving **kin selection**, selection for behaviors that increase the reproductive success of relatives even when they come at a cost to the performer. One example is “helping at the nest” behavior, which was studied extensively in Florida scrub-jays (*Aphelocoma coerulescens*). Scrub-jay pairs mate for life and establish large territories, which they defend aggressively. The mating pair may be assisted in rearing their young by three to five helpers (**Figure 52.18**). The helpers guard against predators, feed the young, clean the nest, and fly with fledglings. Why are these birds helping others rather than rearing their own young? A long-term study established a number of important facts:

kin selection That component of inclusive fitness resulting from helping the survival of relatives containing the same alleles by descent from a common ancestor. (Contrast with direct fitness.)

Figure 52.18 Helpers at the Nest Young Florida scrub-jays often forego reproduction in their first few years of adulthood to help their parents raise their siblings. These

young birds help their parents feed the nestlings, defend the territory, and protect the nest from predators.

The helpers are prior offspring of the mating pair and are usually 1-3 years old.

Young birds that attempt to breed have almost zero reproductive success.

Mating pairs with helpers have approximately three times the reproductive success of those without helpers.

These results support the conclusion that helper scrub-jays are maximizing their inclusive fitness by helping their parents raise siblings until they are mature enough to have a reasonable probability of successfully raising their own offspring.

The concept of kin selection was formalized by W. D. Hamilton in what has become known as **Hamilton's rule**. He argued that, for an apparent altruistic behavior to be adaptive, the fitness benefit of that act to the recipient times the degree of relatedness between the performer and the recipient has to be greater than the cost to the performer. This relationship was clearly stated years before by the eminent geneticist J. B. S. Haldane, who said during an argument about altruism that he would not be willing to risk his life to save his brother, but for two brothers or eight cousins, he would consider it.

Hamilton's rule The principle that, for an apparent altruistic behavior to be adaptive, the fitness benefit of that act to the recipient times the degree of relatedness of the performer and the recipient must be greater than the cost to the performer.

Eusociality is the extreme result of kin selection

Hamilton's rule can be applied to explain **eusociality**: social groups that include nonreproductive members (that is, members that as individuals do not reproduce). The most obvious examples of eusociality occur among the Hymenoptera, an insect group that includes wasps, bees, and ants. In a honey bee colony, for example, the thousands of individuals in the colony are sterile females.

eusocial Pertaining to a social group that includes nonreproductive individuals, as in honey bees.

Media Clip 52.1 Social Shrimps www.Life11e.com/mc52.1

The key to understanding the evolution of eusociality in hymenopterans is their sex determination mechanism, **haplodiploidy**, in which diploid individuals are female and haploid individuals are male. The queen carries a lifetime supply of sperm obtained during her single mating flight, and she controls whether her eggs are fertilized or not. An unfertilized egg develops into a haploid male; a fertilized egg develops into a diploid female. The queen's daughters share all of their father's genes and, on average, half of their mother's genes. As a result, the sterile female workers in the hive—all sisters—share, on average, 75 percent of their alleles (**Figure 52.19**). The basic unit of reproductive success in eusocial insects is the creation of new colonies around a new queen. If a new queen developed from a worker's offspring, the worker would share fewer genes with the new queen than if the new queen developed from a sister.

haplodiploidy A sex determination mechanism in which diploid individuals (which develop from fertilized eggs) are female and haploid individuals (which develop from unfertilized eggs) are male; typical of hymenopterans.

Figure 52.19 Favoring Sisters over Daughters Female honey bees are diploid and males are haploid. Thus if a female worker bee were to reproduce, she would share approximately 50 percent of her genes with her daughters. However, she shares an average of 75 percent of her genes with her sisters. In terms of inclusive fitness, then, a sister is more valuable than a daughter for this species.

Haplodiploidy is not essential for the evolution of eusociality. Nearly all eusocial animals construct elaborate nests or burrow systems within which their offspring are reared. Such a structure represents an enormous investment of resources. Naked mole-rats are eusocial mammals that live in elaborate underground tunnel systems ([Figure 52.20](#)). A colony includes 70-80 individuals but only 1 reproductive female and a few reproductive males. The other colony members are sterile workers that dig and maintain the tunnels, guard against intruders, harvest food (tubers), and use their feces to feed the queen and her offspring. Individuals attempting to found new colonies have a high risk of failing or being captured by predators. When chances of individual reproductive success are practically zero, an individual can best maximize its inclusive fitness by staying with and helping maintain the colony.

Figure 52.20 A Eusocial Mammal Naked mole-rats live in a large colony with one reproductive female and a few reproductive males. Their home is an elaborate tunnel system excavated by the colony over time.

Group living has benefits and costs

Apart from their direct influences on reproductive success, social systems can contribute to survival in many ways, but they can also involve costs. Thus the cost-benefit approach of behavioral ecology is relevant to understanding the evolution of social behavior.

An obvious example of a benefit of group living is improved foraging efficiency. By hunting in packs, African wild dogs (see [Figure 58.17](#)) employ cooperative strategies that enable them to bring down larger prey than could a single dog. The larger the pack, the greater the hunting success rate. Once the prey is killed, the presence of conspecifics also reduces the risk that the wild dogs will lose their prey to larger scavengers, such as hyenas.

Living in a group can also reduce the risk of individuals becoming prey themselves. Many small birds forage in flocks. To test the hypothesis that flocking provides protection against predators, R. E. Kenward released a trained goshawk (*Accipiter gentilis*) near wild common wood-pigeons (*Columba palumbus*) in England. The hawk was most successful when it attacked solitary pigeons. Its success in capturing a pigeon in a flock decreased as the number of pigeons in the flock increased ([Figure 52.21A](#)). The larger the flock, the sooner some individual in the flock spotted the hawk and flew away. This escape behavior stimulated other individuals in the flock to take flight as well.

Figure 52.21 Group Living Provides Protection from Predators Animals that live in groups can spread the cost of looking out for predators. **(A)** The larger the number of common wood pigeons in a flock, the greater the chances that one of the pigeons will spot a predatory goshawk before it attacks, and the lower the chances that the hawk will capture one of the pigeons. **(B)** A male Belding's ground squirrel gives an alarm call upon spotting a predator. Although this behavior increases his individual risk of becoming prey, he increases the survival chances of many of his close relatives.

Alarm calling is another means of reducing predation risk, but the caller incurs a risk cost by calling attention to itself. Belding's ground squirrels (*Urocitellus beldingi*) live in large colonies in open meadows. When one squirrel announces the presence of a predator with loud, sharp barks, all the nearby squirrels dive into their burrows ([Figure 52.21B](#)). Paul Sherman of Cornell University showed that callers double their risk of being preyed on—so why do they do it? Research by Sherman and by others has shown that this altruistic behavior is a product of kin selection. In this polygynous species, males establish large territories in the spring that include the territories of several females, whom they inseminate. The females then drive off the males. Female offspring settle near their mothers, so neighboring females in a colony tend to be sisters, and they defend each other's young. Sherman showed that males are less likely to give alarm calls than females, and that females are more likely to give alarm calls when related individuals are nearby.

Social behavior has many costs as well as benefits. Foraging in a group may reduce the amount of food available to each individual, and the foraging individuals may interfere with one another's foraging activities. Individuals living in groups may face more competition for mates, as well as for food, than solitary individuals would. A large group may actually attract the attention of predators. And living at high population densities can increase the risk of disease transmission. The study of disease transmission in wild animal populations is a relatively new field, but such studies have made it apparent that species living in social groups are more prone

to outbreaks of disease than are solitary species.

Can the concepts of sociobiology be applied to humans?

With the publication of E. O. Wilson's *Sociobiology*, applications of the concepts of evolutionary genetics to human behavior were controversial. The intensity of the debate stemmed from false impressions that sociobiological approaches resembled previously discredited pseudoscientific movements such as social Darwinism, biological determinism, and eugenics, all of which have been used as rationales for racism and discrimination. However, sociobiology is an objective science, questions of "what is" should not be conflated with questions of "what ought to be." For example, we can demonstrate the genetic basis of sexual dimorphism in body size and muscle mass in humans, and we can compare this dimorphism with that in other mammals. However, any attempt to use such data as a political or legal defense for the cultural practice of polygamy would not be science and should not be confused with science.

The fact that our biochemistry, our cell biology, physiology, and anatomy are shaped by our genes is beyond argument. However, it is also clear that these genetically shaped characteristics are also influenced by factors such as environment, nutrition, social interactions, and culture. Why should it be different for behavior? Studies of identical twins reared apart have produced evidence for inheritance of uncanny similarities in behavioral propensities. Studies of isolated human cultures around the world have also revealed remarkable similarities in social organization. None of these studies, however, would challenge the dominant role of learning and culture in the shaping of human behavior.

52.6 recap

Social behavior can be understood by asking how it contributes to the fitness of all the individuals involved. Asymmetry between the sexes in parental investment is a key factor in the evolution of mating systems. According to the theory of kin selection, an individual can increase its fitness by helping related individuals with whom it shares alleles. In extreme cases, kin selection has given rise to eusociality.

learning outcomes

You should be able to:

- Apply concepts of fitness to explain the evolution of social behaviors related to reproduction.
 - Explain how haplodiploidy relates to eusociality.
 - Identify costs and benefits of social behaviors.
-
1. Explain the selective pressures that favor an individual being a helper at the nest rather than engaging in reproduction.
 2. What is the relationship between haplodiploid sex determination and the evolution of eusociality in ants, wasps, and bees?
 3. Many species of small birds respond to the presence of a much larger predator by joining together to mob the predator and drive it off. What do you see as the risks and benefits of this behavior, and what hypotheses could you propose about the individuals taking part in an incidence of mobbing behavior?

QA How does social context influence the learning and expression of birdsong?

Birdsong is the classic example of how genetic determinants, development, physiology, and learning can interact to generate and control even complex behaviors. As you saw with the white-crowned sparrow, the nestlings must experience their species-specific song if they are going to sing it (males) and respond to it (females) as adults. But there is a genetically determined template of what they can and will learn. With physiological maturation, they begin to sing poorly and must hear themselves and practice to be able to sing their species-specific songs. Social context also plays a role in learning small variations of dialects in song that may play a role in population as well as individual identity. Social context also influences what and when singing occurs. Singing intensifies in the presence of competitors and also potential or current mates. The experiments by Woolley and Doupe on zebra finches showed that even though there were only small differences between songs when males sang alone or in the presence of a female, these differences were clearly recognized by females and influenced their behaviors. Studies of birdsong emphasize the importance of considering the evolution of a behavior from the angles of all of the different individuals involved, and at the various levels of biological organization that contribute to the behavior.

Future directions

Language is considered a unique characteristic of humans. Many animals use simple acoustical signals to communicate, but the fine motor control necessary to produce precise, fine-tuned, rapid complex vocalizations is found only in humans and songbirds. Whereas birdsong is recognized to be elaborate but highly stereotyped territorial and mating signals, recent studies like those of Woolley and Doupe are showing that small variations in song can convey more detailed information about the identity of the individual, its intentions, and the social context in which it is behaving. Can birdsong be used to convey more complex information? Can birdsong be a form of simple language? If so, we have much more to learn about the cognitive abilities of birds. Language is used to construct our views of ourselves and of our position in our physical and social environments, and to be able to project those views into the past and into the future—the essence of consciousness. Could birds be better models for human cognitive processes than the mammals typically used in laboratory studies?

► 52.1 Ethology Led to Modern Behavioral Biology

- Ivan Pavlov's discovery of **conditioned reflexes** and B. F. Skinner's research on **operant conditioning** as a model for learning led to an approach called behaviorism that mainly carried out laboratory experiments on rats and a few other animal models. **Review Figure 52.1**
- Ethology focuses on both the **proximate causes** of behavior (the immediate cause of the behavior, and how the behavior develops) and the **ultimate causes** (how the behavior affects the animal's evolutionary fitness).
- A major focus of the ethologists was **fixed action patterns** and their **releasers**. They performed **deprivation experiments** as well as crossbreeding experiments to demonstrate that certain behaviors are genetically determined. **Review Figure 52.2**

► 52.2 Behavior Can Be Genetically Determined

- Genetic manipulations such as gene knockout experiments can reveal the roles of specific genes underlying a behavioral phenotype. **Review Figure 52.3**
- Most behaviors are complex traits involving many genes that function in cascades, offering many points for a change in a single gene to influence behavior. **Review Figure 52.4**

► 52.3 Behavior Can Be Studied Developmentally

- Hormones can determine the pattern of behavior that develops and the timing of its expression. **Review Figure 52.5**
- **Imprinting** is a process by which an animal learns a specific set of stimuli during a limited **critical** or **sensitive period**. That critical period may be determined by hormones.
- The development and expression of song in white-crowned sparrows involve a genetic predisposition to learn the species-specific song, a critical period for imprinting of a song memory, and hormonally controlled timing of song expression. social interactions may also play a role. **Review Figure 52.7**
- The ability to incorporate variations into species-specific behaviors may be important in establishing individuality and influencing mate choice. **Review Investigating Life: Practice Makes Perfect**

► 52.4 Selective Pressures Shape Behavior

- An animal's behavior involves a series of choices that influence its fitness. To make these choices, animals use environmental cues that are reliable predictors of the potential effects of their choice on their fitness.
- The **cost-benefit approach** can be used to investigate the fitness value of specific behaviors. The cost of a behavior typically has three components: **energetic cost**, **risk cost**, and **opportunity cost**. **Review Figure 52.8, Animation 52.1**
- According to **optimal foraging theory**, animals should practice feeding behaviors that maximize their energetic gain at the least cost. **Review Animation 52.2**

► 52.5 Behavior Can Be Studied Mechanistically

- **Circadian rhythms** control the daily cycle of behavior. Without environmental time cues, circadian rhythms free-run with a period that is genetically programmed. Circadian rhythms are normally **entrained** by the environmental light-dark cycle. **Review Focus:** [Key Figure 52.11](#), [Animation 52.3](#)
- Circannual rhythms help organisms time their reproductive behavior to coincide with favorable times of year.
- Forms of navigation used by animals to find their way in the environment include **piloting** (orienting to landmarks), homing, distance-direction navigation, and bicoordinate navigation. Navigation mechanisms include celestial navigation and a time-compensated solar compass. **Review Figures 52.13-52.15**, [Animation 52.4](#), [Activity 52.1](#)
- The behaviors of individuals may become **communication** signals if the transmission of information benefits both the sender and the receiver. Review [Figure 52.16](#), [Activity 52.2](#)
- Chemical communication signals (pheromones) can be highly specific and have different time courses. Visual signals can convey complex messages rapidly, but only if the recipient can see the sender. Acoustic signals can travel over long distances, do not require a focused recipient, and can be modified to reveal or conceal directional information. Tactile signals can convey complex messages when animals are in close proximity.

► 52.6 Social Interactions Shape the Evolution of Behavior

- Differences in parental investment can lead to different mating strategies for males and females.
- **Polygynous** mating systems, in which one male controls and mates with many females, can result in great variation in male reproductive success.
- **Polyandry**—a female mating with multiple males—can evolve in circumstances in which males make substantial contributions to the survival of offspring.
- The fitness an individual gains by producing offspring (**direct fitness**) plus the fitness it gains by increasing the reproductive success of relatives with whom it shares alleles (**indirect fitness**) is called **inclusive fitness**. **Kin selection** may favor **altruistic** behavior toward relatives, despite its cost to the performer, if it increases the performer's inclusive fitness.
- As a result of **haplodiploidy**, the sex determination mechanism of hymenopteran insects, nonreproductive female workers (sisters) share more alleles with one another than reproductive females share with their own offspring. **Review Figure 52.19**
- Haplodiploidy has probably facilitated the evolution of eusocial behavior in the hymenopterans through kin selection. Eusociality has also arisen in diploid species in which chances of individual reproductive success are extremely low.
- Group living confers benefits such as greater foraging efficiency and protection from predators, but it also has costs, such as increased competition for food and ease of transmission of diseases.

Original Paper: Engel, K. C. et al. 2016. A hormone-related female anti-aphrodisiac signals temporary infertility and causes sexual abstinence to synchronize parental care. *Nature Communications* 7: 1-10.

Burying beetles are called nature's undertakers because they bury the remains of small dead animals. These animal bodies serve as food for the beetles' young. A mating pair of beetles typically meets over a fresh animal carcass, copulates, and buries the carcass. The female lays fertilized eggs in the soil above the carcass. Some 50-60 hours later, the eggs hatch and both parents spend the next 3 days eating from the carcass and regurgitating the partially digested material to feed their young. After 3 days, the larvae feed themselves.

Researchers used these beetles to study trade-offs in time and energy investments between brood care and production of new broods. Both activities are demanding, so how do the beetles control their apportionment of energy? The researchers provided female beetles with mating partners and carcasses to stimulate egg laying. There were three treatment groups: (1) no larvae group: just as the eggs hatched, the new hatchlings were removed and the parents were presented with a new carcass; (2) new larvae group: just after their eggs hatched, the parents were left with 10 larvae and given a new carcass; and (3) old larvae group: 4 days after their eggs hatched and they had cared for their hatchlings, the parents were presented with a new carcass. The researchers measured the number of females in each group that produced eggs. The results are shown in [Figure A](#).

The researchers measured juvenile hormone (JH) levels present at various times in the breeding cycles of females with and without larvae. Juvenile hormone is known to suppress the fertility of the females. The results are shown in [Figure B](#).

The researchers also measured the effects of a possible pheromone, methyl geranate, on the beetles' sexual behavior. Methyl geranate is a volatile compound that shares the same biosynthetic pathway with juvenile hormone. The researchers recorded whether or not males copulated with females and the amount of methyl geranate emitted by those females. [Figure C](#) summarizes these results. The data points represent meetings resulting in copulation or not.

Questions

- What do the data in Figure A indicate about energy trade-offs made by female burying beetles? How does this relate to the concept of evolution shaping behavior to maximize fitness? Explain your answer.
- Recall that Tinbergen posed two questions about the proximal causes of behavior and two questions as to the ultimate causes of behavior. For the investigation in Question 1 above, decide which question or questions apply. Do these question(s) deal with proximate or ultimate causes of behavior in burying beetles? Explain your answer.
- What do the data in the Figures B and C indicate about how hormones and pheromones influence burying beetle behavior? What is the biological significance of these results?
- Refer again to the four questions posed by Tinbergen. For the investigations producing the data in Figures B and C, which question or questions apply? Do these question(s) deal with proximate or ultimate causes of behavior in burying beetles? Explain your answer.

2. Give examples of a cost and a benefit of the parental care behavior of burying beetles.

The Largest Experiment on Earth

Most people know that there are many species on Earth, and that new species are being discovered every day, but not everyone knows that roughly half of all species worldwide reside in one place: the tropical rainforests of the Amazon Basin. The statistics are staggering: an estimated 390 billion trees representing 16,000 species grow in Amazonia, one in five bird species globally resides there, and one-fifth of all fresh water falls on its slopes and valleys. The Amazon Basin is by far the largest watershed on Earth, with thousands of tributaries leading to the Amazon River and then out to sea. To date, 2,200 freshwater fish species have been described, which is more than all the fish species in the Atlantic Ocean.

It is reasonable to assume, then, that when the Amazon Basin is threatened by human activities, so, too, is global biodiversity. By far, the main destructive force is deforestation, which began about 50 years ago. As roads pushed their way into Amazonia's forests, more rainforest was logged and converted to agriculture and settlements. It is estimated that nearly 20 percent of the Amazon Basin has been clear-cut. Because soil fertility is generally poor in tropical rainforests, the cleared land is often useful only for a decade or less, resulting in abandonment and new cycles of deforestation and fragmentation.

How does habitat fragmentation affect the species living in the Amazon Basin? Fragmentation makes habitats smaller, and it isolates populations. Deforestation forces species to sustain themselves in a smaller area or move to more suitable areas. In the late 1970s, some ecologists asked a deceptively simple question about Amazon deforestation: What is the minimum area needed to maintain species diversity within a rainforest fragment? They wanted to know whether the species remaining in the forest fragments could maintain themselves there, whether the sizes of the forest fragments mattered to this maintenance, and whether species would venture from one fragment to another. These ecologists conducted a large and long-running experiment in the Amazon forests near Manaus, Brazil. As you will see in [Key Concept 53.5](#), the size of the fragments and the ability of species to move across the deforested landscape are key to maintaining the extraordinary diversity left in the Amazon Basin.

How do geographic area and isolation affect the biogeography of life on Earth?

53.1 Ecology Is the Study of the Interrelationships among Organisms and the Environment

Whether you notice ants collecting crumbs on a sidewalk or watch a video of polar bears hunting on sea ice, you are studying ecology. From simple experiences such as these, most people know that organisms on Earth are interconnected with one another and with their environment. **Ecology** is the exploration of these interconnections and is most simply defined as the study of the interrelationships among organisms and the physical environment. Ecologists study these interactions at different scales and with different methods, but they all agree that ecology is a scientific endeavor, first and foremost.

ecology [Gk. *oikos*: house] The scientific study of the interrelationships of organisms with their living (biotic) and nonliving (abiotic) environments.

focus your learning

Ecology is the study of the interrelationships among organisms and the physical environment.

Ecology uses observations, experiments, and models to test theories at multiple spatial and temporal scales.

“Ecology” is sometimes equated with “environmentalism,” but the two terms are different. Ecology is a science that generates knowledge about interactions in the natural world.

Environmentalism is the use of ecological knowledge, along with economics, ethics, and many other considerations, to inform both personal decisions and public policy related to stewardship of the natural world. So while an ecologist might study the number of bluefin tuna in the world’s oceans, the environmentalist would focus on the social, economic, and political capital needed to enforce a sustainable harvest or, alternatively, to ban bluefin tuna fishing altogether.

environmentalism The use of ecological knowledge, along with economics, ethics, and many other considerations, to inform both personal decisions and public policy relating to stewardship of natural resources and ecosystems.

Ecology is a relatively new branch of the biological sciences; in fact, it did not have a formal name until 150 years ago when Ernst Haeckel, a German biologist, constructed the new word “ecology,” from the Greek root *oikos*, or “household.”

Modern ecology has a more “use-inspired” focus

Although it was recognized in Darwin’s day that humans could affect the natural world, and that human populations were undergoing unprecedented growth, for the most part early ecologists believed they were studying pristine systems largely untouched by human activities. Today most ecologists have a much greater awareness of ways in which humans shape the natural world, be it in the form of global climate change, the introduction of novel species to new locations, or

the logging of Earth's tropical forests. Because of the dominant role that humans play in almost every ecological system on Earth, a "use-inspired" motivation often shapes ecologists' research and teaching. They understand that scientific knowledge of ecology greatly improves our ability to grow food for ourselves reliably and sustainably, to manage pests and diseases safely and effectively, and to deal with natural disasters such as floods and fires. The greater our understanding of ecological connections, the more likely it is that we can accomplish these things without causing a cascade of unanticipated consequences for ourselves and the other life on Earth.

Ecology is studied at many levels of organization

Ecology is studied at many levels of organization, from molecules to the entire globe. Some ecologists work at the level of genes to understand how individuals might adapt to a changing environment, while other researchers seek to understand how temperature might modify nutrient cycling at the ecosystem level. The work of ecologists focuses on many scales or levels of organization: individuals, populations, communities, ecosystems, landscapes, or the global biosphere ([Figure 53.1](#)).

Figure 53.1 Scale Is Important to Ecological Systems These photos from the Oregon coast of the United States illustrate how ecological systems can be studied at a number of scales, from the individual to the biosphere.

As prior chapters have conveyed, a **population** is a group of individuals of the same species

within a given area that have the potential to interbreed and interact with one another. For example, the individual seastars in [Figure 53.1](#) make up a population at this particular rocky shore location. The seastar population in turn interacts with other species, including its prey, sessile mussels, and its competitors, whelks and other seastar species. These species form a **community**, which is an assemblage of interacting species living together at the same place and time.

population (1) In biology, any group of organisms coexisting at the same time and in the same place and capable of interbreeding with one another. (2) In statistics, a study group of interest.

community A group of species living together at the same place and time.

Ecological studies often encompass both the living, or **biotic**, and the nonliving, or **abiotic**, components of the environment. The biotic components of an organism's environment are other organisms, so ecology includes the study of interactions within and among species. The abiotic components of an organism's environment are the myriad physical and chemical characteristics of the system. For example, in the rocky shore community, tides are a key abiotic factor because they limit where seastars can feed on mussels and compete with whelks.

biotic (bye ah' tick) [Gk. *bios*: life] Living components of the environment such as organisms. (Contrast with abiotic.)

abiotic (a' bye ah tick) [Gk. *a*: not + *bios*: life] Nonliving components of the environment including its physical and chemical characteristics. (Contrast with biotic.)

The term **ecosystem** is often used when describing a community of organisms in which their physical environment is explicitly taken into account. Ecosystem ecology particularly focuses on the movement of energy and nutrients through a group of organisms. The movement of energy and nutrients, as well as organisms, can affect higher levels of organization, including **landscapes**, geographic areas that include multiple ecosystems (sometimes referred to as meta-ecosystems). Ultimately, meta-ecosystems are linked to one another at larger geographic scales to form the **biosphere**, consisting of all living organisms on Earth plus their respective environments.

ecosystem (eek' oh sis tum) The organisms of a particular community together with the physical and chemical environment in which they live.

landscape A geographic area consisting of multiple ecosystems or habitats.

biosphere (bye' oh sphere) All regions of Earth (terrestrial and aquatic) and Earth's atmosphere in which organisms can live.

Answering ecological questions requires observations, experiments, and models

Just as in other fields in biology, ecologists use a mixture of observations, experiments, and models to test ecological theories (see [Key Concept 1.2](#)). Ecologists are unique, though, in using a wide range of venues and scales in their experiments, including short laboratory experiments, long-term field manipulations, and even decades-long ecosystem-wide experiments, such as the Biological Dynamics of Forest Fragments Project described in [Key](#)

[Concept 53.5](#). However, at large spatial scales or over long periods of time, well-replicated and controlled experiments are usually not possible. For example, when studying the ecological effects of climate change on a particular species, ecologists might have to combine observations of the temperature range of that species with short-term experiments on the effects of warming on the species' distribution and then use models to project how distributions could change with continued warming. Often this type of research requires multiple techniques and collaborative efforts to be successful.

53.1 recap

Ecology is the scientific study of the interrelationships among organisms and the environment. Ecology is studied at multiple levels of organization, from individuals to the biosphere. Ecologists use a mixture of observations, experiments, and models to test ecological theories.

learning outcomes

You should be able to:

- Distinguish between ecology and environmentalism, and include examples of each.
- Describe the methods of study used by ecologists, and identify how and why ecological studies might differ from studies in other scientific fields.

1. How does ecology differ from environmentalism? Give a reason why ecology is a useful scientific enterprise.
2. Using observations, experiments, and models at different levels of organization, describe how you might test the hypothesis that the widespread death of the ochre sea star (*Pisaster ochraceus*) (shown in [Figure 53.1](#)) is the result of a disease.

We will begin our study of ecology in the spirit of the discipline in Haeckel's time, focusing on variations in the distribution and abundance of organisms worldwide and the factors that determine these patterns. Our first step will be to examine attributes of the physical environment, which is the ultimate determinant for where organisms can live. We'll begin with climate.

53.2 Global Climate Is a Fundamental Component of the Physical Environment

The terms “weather” and “climate” both refer to atmospheric conditions—temperature, humidity, precipitation, and wind direction and velocity—but they consider different time scales. [Weather](#) is the short-term state of atmospheric conditions at a particular place and time, whereas [climate](#) refers to the average atmospheric conditions, and the extent of their variation, at a particular place over a longer time (years to millennia).

weather The short-term state of atmospheric conditions (temperature, precipitation, humidity, wind direction and velocity) at a particular place and time. (Contrast with climate.)

climate The long-term average atmospheric conditions (temperature, precipitation, humidity, wind direction and velocity) at a particular place over longer time (years to millennia). (Contrast with weather.)

focus your learning

“Weather” and “climate” refer to atmospheric conditions at different time scales.

Earth’s spherical shape creates latitudinal variation in solar radiation absorption and thus differences in temperature and precipitation; the proportion of land to ocean is also important.

Earth’s rotation around its axis deflects air and water and creates prevailing winds and ocean currents.

The tilt of Earth’s axis and its orbit create seasons.

Climate is what you expect given past conditions; weather is what you get on any one day. For example, a warming climate will cause glaciers to melt over decades or centuries (see [Figure 1.16](#)), whereas a single large snowstorm is unlikely to thwart that retreat. In addition, the responses of organisms to weather are usually short-term—seeking shelter from a sudden rainstorm, for example, or shivering to keep warm when the temperature drops. Climate, by contrast, acts as a sort of filter for organisms, ultimately determining their distribution and abundance. If organisms cannot tolerate the climate of a particular place, they will not be found there. What are the processes that create global climate patterns?

Solar radiation drives global climate patterns

The energy that drives global climate patterns ultimately originates from the sun. Of the solar radiation that hits Earth, about 30 percent is reflected back to space by clouds, atmospheric gases, and Earth’s surface ([Figure 53.2](#)). The rest is absorbed either by the atmosphere (20%) or the surface of Earth (50%). The [atmosphere](#), a thin layer of gases surrounding Earth composed of nitrogen gas (N₂, 78%), oxygen (O₂, 21%), argon (0.9%), carbon dioxide (CO₂, 0.037%), and traces of hydrogen, helium, ozone, methane (CH₄), and many other gases, moderates Earth’s surface temperatures by trapping heat energy. If Earth had no atmosphere, its average surface temperature would be about –18°C, rather than its actual +17°C. Carbon dioxide, methane, nitrous oxide (N₂O), water vapor, and certain other gases in the atmosphere

are known as **greenhouse gases** because they allow sunlight into Earth's atmosphere but trap heat radiating back out toward space (see [Figure 53.2](#)).

Figure 53.2 Radiant Energy Warms the Planet Solar energy input (yellow arrows) is absorbed by Earth's atmosphere and surface. Much of this energy is radiated from Earth's surface in the form of heat (orange arrows). Of that absorbed at the surface, most is prevented from escaping back into space by greenhouse gases in the atmosphere. The widths of the arrows are roughly proportional to the sizes of the energy fluxes.

Q: What effect do greenhouse gases have on Earth's energy balance?

atmosphere A thin layer of gases surrounding Earth composed of nitrogen gas, oxygen, argon, carbon dioxide, and traces of hydrogen, helium, ozone, methane, and many other gases.

greenhouse gases Gases in the atmosphere, such as carbon dioxide and methane, that are transparent to sunlight, but trap heat radiating from Earth's surface, causing heat to build up at Earth's surface.

 Animation 53.1 Radiant Energy Balance www.Life11e.com/a53.1

The amount of radiation received on Earth varies with latitude and with the seasons. These differences are driven by some well-known characteristics of Earth: it is a sphere that orbits the sun, it spins on a tilted axis, and it has both land and water. As you will see, it is the combination of these factors that determines the climate we experience on Earth.

Earth is a sphere, creating latitudinal variation in global temperature and precipitation

Because Earth is a sphere, the intensity of solar radiation hitting its surface varies with latitude. This latitudinal variation in solar energy depends primarily on the angle of the sun's rays striking Earth. At high latitudes (i.e., areas toward the North and South poles), incoming solar energy is distributed over a larger area (and thus is less intense) than at the equator, where sunlight strikes the surface perpendicularly ([Figure 53.3](#)). Moreover, when the sun's radiation comes in at an angle, it must pass through more of Earth's atmosphere, resulting in more of its energy

being absorbed or reflected before reaching Earth's surface. Differences in solar energy input explain why the average global temperature varies with latitude, with warmer temperatures at the equator and colder temperatures at the poles ([Figure 53.4A](#)). The average air temperature over the course of a year decreases about 0.76 °C for every degree of latitude (about 110 km) at sea level.

Figure 53.3 Solar Energy Input Varies with Latitude The angle of incoming sunlight affects the intensity of solar energy that reaches a given unit of Earth's surface.

(A) Average annual air temperature

(B) Average annual precipitation

Figure 53.4 Global Temperature and Precipitation Vary with Latitude Average annual air temperature **(A)** and precipitation **(B)** vary with Earth's latitude but can be modified by topography (i.e., Earth's shape and surface features) (see [Figure 53.9](#)).

In addition to there being a latitudinal variation in temperature, the Northern Hemisphere is slightly warmer (by $\sim 2^{\circ}\text{C}$) and more variable in temperature (by a range of $\sim 7^{\circ}\text{C}$) than the Southern Hemisphere (see [Figure 53.4A](#)). Although the reasons for this difference are uncertain, one hypothesis is that because land heats up the air above it more than does the ocean (which absorbs more heat), the greater proportion of land to ocean in the Northern Hemisphere creates warmer air temperatures than those in the Southern Hemisphere. This is particularly true in summer, when the temperature difference is at its greatest. In light of global warming, it is worth noting that temperatures are increasing faster in the Northern Hemisphere than in the Southern Hemisphere.

Besides controlling temperature, solar energy input also determines atmospheric circulation

and associated precipitation patterns. As you saw earlier, air in the region surrounding the equator receives the greatest input of solar energy. When a parcel of air is warmed, it expands, becomes less dense, and rises (see [Figure 53.5A](#)). As it rises, however, it starts to cool at higher elevations. Cool air cannot hold as much water vapor as warm air, so the expanding, cooling air releases moisture in the form of precipitation. This is particularly evident in the tropics, where there is abundant rainfall year-round ([Figure 53.4B](#)). Eventually the rising air at the equator reaches the boundary between the troposphere, the atmospheric layer above Earth's surface, and the stratosphere, the next layer up. The stratosphere is warmer than the troposphere at this boundary, causing the tropical air to stop rising and eventually move either north or south as newly warmed air rises to replace it ([Figure 53.5A](#)). Eventually this air starts to cool as it exchanges heat with the atmosphere and meets colder air traveling from higher latitudes. When this cool, dry air, which lost its moisture as it rose over the equator, reaches latitudes of about 30°N and 30°S, it begins to sink under high atmospheric pressure, making the climate at these latitudes dry ([Figure 53.5B](#)). Earth's great deserts—including the Sahara of Africa, the Gobi of China, and the deserts of Australia and the American Southwest—are located at these latitudes (see [Figure 53.4B](#)).

While some of the descending air flows back toward the equator, some of it flows toward the poles, setting up another atmospheric cell of air circulation at higher latitudes. At about 60° latitude, air rises again due to its warming at Earth's surface (see [Figure 53.5B](#)). As this air rises, it cools and releases precipitation, creating wet climate conditions at temperate latitudes. Eventually this air reaches the stratosphere and moves north or south. The cold, dry air traveling at higher latitudes eventually reaches the cold polar region, where it descends. Despite the amount of snow and ice at the poles, high latitudes at or near 90 ° actually receive little precipitation and can be thought of as “polar deserts” (see [Figure 53.4B](#)).

Earth spins on an axis, producing prevailing winds and ocean currents

You have seen that Earth's spherical shape creates predictable patterns of temperature and precipitation, but Earth's rotation, which moves east to west, is responsible for generating global wind and ocean currents. Because Earth is a sphere, the velocity of its rotation around its axis is fastest at the equator, where its diameter is greatest, and is slowest close to the poles. This difference creates the [Coriolis effect](#), which is the deflection of air or water as a result of differences in Earth's rotational speed at different latitudes. For example, air traveling toward the equator (driven by the circulation patterns described above and in [Figure 53.5](#)) moves at a slower speed than that of the planet beneath it and is thus deflected to the west. Conversely, air traveling toward either pole is moving faster than that of the surface beneath it and is deflected to the east. This interaction of Earth's rotation and north-south air mass movement sets up a pattern of circulating surface air referred to as [prevailing winds](#) ([Figure 53.6](#)). Prevailing winds blow from east to west in the tropics (the [trade winds](#)); from west to east in mid-latitudes (the [westerlies](#)); and from east to west again above 60 °N or 60 °S latitude (the [easterlies](#)).

Coriolis effect The deflection of air or water as a result of differences in Earth's rotational speed at different latitudes.

prevailing winds The circulation of air (wind) that moves across the Earth's surface in a predominately single direction.

trade winds Prevailing winds that blow from east to west across the tropics.

westerlies Prevailing winds that blow from west to east across the mid-latitudes. (Compare with easterlies.)

easterlies Prevailing winds that blow from east to west at high latitudes. (Compare with westerlies.)

Figure 53.5 Air Circulation in Earth's Atmosphere Drives Climate (A) Solar energy drives patterns of atmospheric circulation. (B) The differential heating of Earth's surface by solar radiation gives rise to atmospheric circulation cells, which influence atmospheric pressure, air temperatures, and precipitation worldwide.

Figure 53.6 Prevailing Winds Created by Earth's Rotation and Atmospheric Circulation The deflection of air as a result of differences in Earth's rotational speed at different latitudes (also known as the Coriolis effect) coupled with atmospheric

circulation of air masses combine to create a global pattern of prevailing surface winds across the planet.

How, then, are the circulation patterns of ocean currents generated? Ocean currents are driven by prevailing winds, which move water by means of frictional drag. The trade winds, for example, cause currents to converge at the equator and move westward until they encounter a continent ([Figure 53.7](#)). At that point, the strong Equatorial Countercurrent brings some of the water back eastward. The remaining water divides, some moving northward and some southward along continental shores. These patterns of water movement set up rotating circulation patterns called **gyres** (Greek *gyros*, “spiral”), which rotate clockwise in the Northern Hemisphere and counterclockwise in the Southern Hemisphere.

Figure 53.7 Oceanic Circulation Created by Winds and Continents The surface currents of the ocean are driven by the prevailing winds (see [Figure 53.6](#)), Earth’s rotation, and the placement of the continents. Red arrows indicate warm surface water, and blue arrows indicate cold surface water.

gyres Large-scale circular ocean currents caused by prevailing winds and Earth’s rotation.

Because ocean currents transport heat, they have a tremendous effect on Earth’s climates. The poleward movement of warm water from the tropics transfers large amounts of heat to high latitudes. The Gulf Stream, for example, carries warm water from the tropical Atlantic Ocean (including the Gulf of Mexico) north across the Atlantic to northern Europe, making Europe’s climate considerably milder than that of corresponding latitudes in North America. Similarly, currents flowing toward the equator from high latitudes bring cool, wet winters to some western coastal regions that are otherwise warm and dry.

The tilt of Earth’s axis and its orbit result in seasons

The tilt of Earth’s axis, coupled with Earth’s orbit around the sun, is responsible for seasonal changes in climate. Earth’s axis is tilted at an angle of 23.5 degrees, changing the amount of sunlight a particular region receives over the course of a year as Earth orbits the sun ([Figure 53.8](#)). This tilt causes seasonal variation in temperature and day length. Higher latitudes experience greater seasonal variation than lower latitudes do. Around the equator, day length and seasonal temperatures change only slightly over the course of the year, although there are

seasonal shifts in precipitation patterns.

Figure 53.8 Seasonal Change Is the Result of the Tilt of Earth's Axis and Its Orbit Because Earth's axis of rotation is tilted, orientation relative to the sun changes over the course of a year as the planet orbits the sun. The resulting variation in solar radiation creates seasonal climate variation.

53.2 recap

Climate and weather both refer to atmospheric conditions, but climate represents conditions over years whereas weather includes conditions over a span of days. Earth is a sphere, has an atmosphere, and rotates around its axis, which creates latitudinal variation in solar radiation, temperature and precipitation, and prevailing winds and ocean currents. Earth's tilt and orbit around the sun result in the seasons.

learning outcomes

You should be able to:

- Compare weather and climate, and give examples of both.
- Analyze differences in temperature at the equator and the poles as a function of Earth's spherical shape.
- Relate Earth's ocean currents to prevailing wind patterns, and explain how ocean currents affect climate.
- Connect the tilt of Earth's axis and its orbit to the existence of seasons on Earth, and explain why the Northern and Southern Hemispheres have opposite seasonal patterns.

1. Does a month of extremely hot weather tell us that Earth's climate is warming? Explain

your answer.

2. Why does solar energy input into Earth's atmosphere vary with latitude? What are the consequences for global climate?
3. Refer to [Figures 53.6](#) and [53.7](#). If you were sailing, using wind power only, from the east coast of North America to Europe across the Atlantic Ocean, describe the best route given winds and currents.
4. Explain why Earth's Northern and Southern Hemispheres have opposite seasons.

We have considered large, global patterns in climate, but we know that the physical environment can vary within certain regions or even locally. Just travel across a large mountain range and you can experience lush forests on one side and bone-dry deserts on the other. We next turn to what controls smaller, more regional and local variation in the physical environment, both on land and in water.

53.3 Topography, Vegetation, and Humans Modify the Physical Environment

Three main factors can modify the pattern of global climate, determining regional and local variation in climate and other aspects of the physical environment: (1) Earth's topography, (2) vegetation, and more recently, (3) the effects of humans.

focus your learning

Mountains and other land-based topographic features influence regional and local physical conditions.

Ocean-floor topography affects water depth, which in turn affects light penetration, water temperature, water pressure, and water movement.

Human infrastructure and agriculture have transformed half of Earth's area.

Earth's topography affects the local and regional physical environment

Earth's topography, meaning its shape and surface features, has been formed over geological time and provides the basis for much of the variation in local and regional physical conditions. Here we consider how topography modifies the physical environment with respect to land, oceans, rivers, and lakes.

LAND

The topography of land plays a large role in the regional and local physical environment, including climate. Mountains create elevational gradients in temperature, precipitation and sunlight. For example, mountains show progressively colder temperatures and greater precipitation at higher elevations, creating different environmental conditions over relatively short distances. When a mountain range occurs adjacent to an ocean, a [rain shadow](#) is often created, where one side of the mountain has a wet climate and the other side has a dry climate ([Figure 53.9A](#)). Rain shadows occur when winds deliver moist air evaporated from the ocean to the windward side of the mountain, where the air rises, cools, and releases rain or snow. On the leeward side of the mountain (that is, opposite from the direction of the winds), the now-dry air descends, warms, and produces arid conditions. The High Desert, on the leeward side of the Cascade Range in the Pacific Northwest of the United States, is one such area.

rain shadow The relatively dry area on the down-wind side of a mountain range.

(A) Rain shadow

(B) Temperature inversion

(C) Aquatic zones

(D) Ocean upwelling

Figure 53.9 Effects of Earth's Topography on the Physical Environment Earth's topography can affect both land and oceans. Mountains and valleys create **(A)** rain shadows and **(B)** temperature inversions. Ocean topography affects water depth, which **(C)** creates aquatic zones that vary in light, temperature, and water pressure, and **(D)** along with wind, produces ocean upwelling.

Q: What kind of weather conditions would you expect to produce temperature inversions?
How about ocean upwelling?

Other topographic features, such as canyons and valleys, also modify local climate in significant ways. Valleys can experience [temperature inversions](#), extremes in temperature that produce morning fog and intense afternoon heat. Temperature inversions occur when the valley concentrates heat from solar radiation during the day. As that heat rises, it forms an inversion layer that traps cold, dense, and moisture-laden air that descends into the valley overnight and produces fog ([Figure 53.9B](#)).

temperature inversions Foggy conditions created when cold air is trapped within a warm inversion layer that forms over valleys during warm days.

OCEANS

Beneath the oceans, which make up 70 percent of Earth's surface, dramatic differences in topography influence the marine environment. If you could drain the oceans, you would notice major differences in topography, ranging from the Hawaiian island Mauna Loa, the tallest "mountain" on Earth at 9,170 meters high from base to peak, to the Marianas Trench, the deepest "valley" at 10,994 meters deep. Variations in water depth affect light penetration, water

temperature, water pressure, and water movement (i.e., waves and tides). These physical discontinuities create distinct zones that are identified principally by their physical conditions and the characteristic biota they contain, similar to biomes on land (see [Key Concept 53.4](#)). The depth of an ocean basin varies from the shoreline to the relatively shallow continental shelf and to the deepest part of the ocean, sometimes known as the abyssal plain ([Figure 53.9C](#)). Water depth affects how much light is available to sustain the photosynthetic organisms that form the base of the marine food chain. In both marine and freshwater environments, roughly 90 percent of all aquatic life is found in the [photic zone](#), the layer of water reached by enough sunlight to support photosynthesis.

photic zone The life zone in lakes and oceans that is penetrated by light and therefore supports photosynthetic organisms.

Other zones that vary in environmental conditions include the coastal zone, which extends from the shoreline to the edge of the continental shelf, and the [ocean zone](#), which extends beyond the [coastal zone](#) (see [Figure 53.9C](#)). The coastal zone is diverse and highly productive, supporting high densities of pelagic, or floating, plankton and fish. On the benthic or bottom of the ocean, the coastal zone has a variety of living and nonliving habitats such as rocky reefs, soft sediment flats, coral reefs, and kelp beds. The portion of the benthic coastal zone lying between the high and low tide levels is the [intertidal zone](#), where tidal movements create conditions of highly variable light and temperature, alternately exposing organisms to air and water. Intertidal zones can occur on the open coast as sandy or rocky beaches, or in more protected bays as estuaries. [Estuaries](#) form where rivers meet the sea, creating variability in salinity, sediment, and light conditions.

ocean zone The marine life zone that extends from the coastal zone into open ocean. Characterized by deep water that varies in its oxygenation and relatively stable temperatures and salinities.

coastal zone The marine life zone that extends from the shoreline to the edge of the continental shelf. Characterized by relatively shallow, well-oxygenated water and variable temperatures and salinities.

intertidal zone A nearshore region of oceans that is periodically exposed to the air as the tides rise and fall.

estuary An aquatic habitat in which salt water and fresh water mix, as when a river meets the ocean. Includes such ecosystems as salt marshes, mangrove forests, mudflats, and seagrass beds.

In some coastal zones, where the continental shelf is steep and prevailing winds are parallel to the coastline, [upwelling](#) can affect ocean and climate conditions. Upwelling is a process in which offshore winds in combination with the Coriolis effect push warmer surface waters away from the shore, allowing deeper, colder, and nutrient-rich bottom water to rise to the surface ([Figure 53.9D](#)). Upwelling affects local and regional climate on the coast by creating cooler and moister conditions. In addition, upwelled waters support high rates of primary production by phytoplankton, which in turn support dense consumer populations. Most of the world's great fisheries are concentrated in upwelling zones.

upwelling A process by which offshore winds in combination with the Coriolis effect push

warmer surface water away from the shore, allowing cold, nutrient-rich water from deeper waters to rise to the surface.

As we move away from the coastline, most of the ocean's physical environment is made up of vast amounts of water that is, with the exception of the photic zone (which can extend to 200 meters in some regions), mostly dark, cold, and under tremendous pressure from the weight of the water above. Little photosynthesis can take place, and many of the organisms inhabiting these regions subsist on decaying organic matter that sinks down from the photic zone. Deepocean trenches and rift valleys support hydrothermal vent ecosystems sustained by chemoautotrophic prokaryotes that can metabolize the nutrients without the aid of sunlight (see [Key Concept 25.3](#)).

RIVERS AND LAKES

In contrast to the vast oceans, freshwater lakes and rivers make up less than 3 percent of Earth's surface, but they are home to about 10 percent of all aquatic species. Earth's topography influences freshwater environments just as it does in the oceans—through the depth of the water—but it also influences the degree and direction of movement of fresh water. A river is water that flows downhill from its point of origin (the source) over the land surface as a result of gravity until it reaches either the ocean or a depression in Earth's surface, where it forms a lake or pond. The headwaters (those close to the source) tend to be cool, fast-flowing, and well oxygenated. As a river flows downstream, it widens, it slows down, it warms, and sediment accumulates, reducing light penetration and oxygen levels.

The Amazon River, mentioned in the chapter opening, offers a dramatic example of river dynamics. The Amazon is one of the longest rivers on Earth, at approximately 7,000 km. Eventually this source water reaches the Atlantic Ocean, where discharge is the largest of any river on Earth—the Amazon's mouth is 240 km wide and is referred to as “the River Sea.”

Vegetation affects the local and regional physical environment, especially climate

Earth's climate would be very different without the influence of organisms, including humans. Organisms can “engineer” the environment in multiple ways that affect the surrounding climate and physical conditions. The most obvious influence comes from vegetation, especially forests, which can have large effects on temperature and precipitation at local and even regional scales. For example, measurements of energy exchange in tropical forests that have been converted to pastureland show that forests make the climate cooler and moister ([Figure 53.10](#)). While forests absorb heat by reflecting less sunlight (reflection of solar radiation is known as the [albedo effect](#)) and decrease convective heat loss by acting as a wind screen, this is more than balanced by the cooling effect produced by evapotranspiration: the evaporative transfer of heat and water from the surfaces of plants into the atmosphere, which reduces air temperature and increases moisture. When forests are cut and replaced by vegetation such as grasses, the albedo effect and convective heat loss intensify while evapotranspiration decreases, causing overall air temperatures to rise and precipitation to decrease, creating more arid conditions. The climate changes associated with deforestation have been seen in the Amazon Basin, where massive forest clearing makes way for cattle ranching.

Figure 53.10 Deforestation Can Affect Climate Evapotranspiration by trees reduces air temperatures and increases precipitation. When land is deforested and the trees are gone, the cooling effects of the albedo (reflection of solar radiation) and of convective heat loss are not enough to outweigh the warming effects of reduced evapotranspiration. The widths of the arrows are roughly proportional to the sizes of the fluxes.

albedo effect (al bee' doh) [L. *albus*: white] The solar radiation reflected by the surface of Earth.

Oceans have their own “forests”—coastal areas dominated by seaweeds such as giant kelps or seagrasses that create calmer waters, promote sedimentation, and provide habitat for fish and invertebrates. In warmer coastal waters, corals generate complex reef structures that support ecosystems rivaling rainforests in diversity. In [Chapter 56](#) you will learn more about organisms that engineer their environment, but for now let's turn to the final topic in this section: the effects of humans on climate and the physical environment.

Humans have transformed their physical environment, including urban climate

It is estimated that humans have transformed more than 50 percent of Earth's land surface, replacing it with infrastructure and agriculture needed to support our burgeoning population. You have already seen how the conversion of forestland to pastureland can change regional climate, and in [Chapter 57](#) you will learn more about how humans have changed global climate through the burning of fossil fuels. Structures such as dams, bridges, and nuclear power plants can dramatically transform rivers and lakes. Urban areas, in particular, modify not only the immediate physical environment but also the surrounding climate. A survey of 60 U.S. cities in 2014 showed that urban summer temperatures were on average 1.5 °C hotter than rural summer temperatures, with the top 10 cities having an average urban-rural temperature differential of 5 °C. The cause of this so-called urban heat island effect is simple: concrete, asphalt, and even the dark roofs of buildings absorb heat from solar radiation and radiate that heat in the evening hours ([Figure 53.11](#)). Cities also produce more heat through the burning of fossil fuels from cars, factories, and buildings. Parks can serve to cool the surrounding air through the evapotranspiration of trees and other vegetation. In addition, the temperature differential between cities and the surrounding countryside can create “country breezes,” air movement generated as rising warm air from the city is replaced by cold surface air from surrounding rural areas.

Figure 53.11 Cities Can Create Heat Islands and Country Breezes As this hypothetical urban heat island profile shows, cities and suburbs typically have higher temperatures than rural, park, or agricultural areas. Country breezes form when warm air from cities and suburbs is replaced by cool air from rural areas.

53.3 recap

Earth's topography is responsible for rain shadows and temperature inversions, producing variation in temperature and precipitation. In the oceans, topographical variability produces differences in water depth, which affects light penetration, water temperature, water pressure, and water movement. Vegetation, especially forests, affects climate through the process of evapotranspiration. Humans have transformed urban climate; cities are on average hotter than rural areas.

learning outcomes

You should be able to:

- Explain and compare the causes and effects of rain shadows and temperature inversions.
- Explain why ocean-floor topography is important in determining the marine environment.
- Describe and contrast ways in which agriculture and human infrastructure (such as urbanization) may transform local and regional climates.

1. What are some of the major ways that Earth's topography affects land and ocean physical conditions?
2. Why are cities warmer than rural areas, and what are country breezes? How and why could the temperature within a city be changed with the establishment of a large forested park?

With an understanding of how Earth's physical environment, including climate, is determined at a variety of spatial scales, we turn next to biogeography: how the physical environment and

other geographic and historical processes determine the global distribution of organisms on Earth.

53.4 Biogeography Is the Study of How Organisms Are Distributed on Earth

Biogeography is the scientific study of the distribution and diversity of organisms on Earth. “Distribution” is simply where organisms are found. “Diversity,” however, has multiple facets, which we will explore in more detail in [Chapter 56](#), but for now you can think of it simply as the number and composition of species or higher taxa. For centuries, the processes that control these biogeographic patterns have puzzled naturalists. Why do species vary in their distributions around Earth, and what controls this variability?

biogeography The scientific study of the distribution and diversity of organisms across Earth.

focus your learning

Biomes cross continents, occurring where climatic conditions are similar. Earth’s major biomes include tropical rainforests, deserts, temperate grasslands, temperate deciduous forests, temperate evergreen forests, boreal forests, and tundra.

Alfred Russel Wallace observed distributional differences in biota on the Malay Archipelago that led to his theory of biogeography.

Hypotheses to explain the causes of latitudinal variations in diversity include species diversification rate, species diversification time, and productivity.

Patterns of biogeography are interconnected across a hierarchy of spatial and temporal scales

The patterns of biogeography play out over global, regional, landscape, and local spatial scales (**Focus: Key Figure 53.12**). Spatial scales are interconnected in a hierarchical way, with patterns at one scale setting the conditions for patterns at other scales.

focus: key figure

Figure 53.12 Biogeography Depends on Interconnected Spatial and Temporal Scales The arrows represent the relationship between, and processes important to, species diversity and composition at **(A)** global, **(B)** regional, **(C)** landscape, and **(D)** local scales.

Q: At what scales is the regional species pool important to species diversity and composition?

At the global scale, species are isolated from one another by continents or oceans, and for long periods of time. Thus the rates of three processes—speciation, extinction, and dispersal—help determine differences in biogeography across the globe (see [Figure 53.12A](#)). At the regional scale, large-scale climate conditions are relatively uniform and species are limited by their ability to disperse, or move between locations (see [Figure 53.12B](#)). All the species that are limited to a region are part of the **regional species pool** (also called **gamma diversity**). At the landscape scale, there are multiple community types—for example, lakes, rivers, forests, and prairies—arranged in a spatially heterogeneous way across the region (see [Figure 53.12C](#)). The change in the number of species from one community to another across the landscape is known as **beta diversity**. Finally, the local scale (also called **alpha diversity**) typically encompasses a single community—a group of species assembled together as the result of the physical environment, biotic interactions with other species, and the regional species pool (see [Figure 53.12D](#)).

regional species pool All the species that are limited to a geographic region; sometimes called gamma diversity.

gamma diversity Species diversity within a geographic region; the regional species pool. (Compare with alpha diversity, beta diversity.)

beta diversity The change in species number and composition, or turnover of species, across a landscape. (Compare with alpha diversity, gamma diversity.)

alpha diversity Species diversity at the local or community scale. (Compare with beta diversity, gamma diversity.)

In the remainder of this chapter we will consider the distributional and diversity patterns of organisms at global and regional biogeographic scales. [Chapter 56](#) will consider the causes and consequences of diversity at community and local scales.

Terrestrial biomes reflect global patterns of temperature and precipitation

Biomes are groupings of ecologically similar organisms shaped by the environment in which they are found. The classification of biomes is most often and easily applied to terrestrial systems. Ecologists classify terrestrial biomes principally by the growth forms of their dominant plants, which reflect the evolution of those plants under annual patterns of temperature and precipitation.

biome (bye' ome) A major division of the ecological communities of Earth, characterized primarily by distinctive vegetation and the annual patterns of temperature and precipitation. A given biogeographic region contains many different biomes.

The same classic types of biomes may be widely separated, occurring on different continents, depending in large part on the presence of suitable climatic conditions ([Figure 53.13](#)). For example, the desert biome occurs in such distant locations as Arizona in the North American Southwest and the Namib Desert in Africa; both locations are extremely dry and dominated by succulent plants such as cacti and by drought-tolerant shrubs and grasses. Why use plants as a way of classifying biomes? Because plants are immobile, they must adapt to environmental conditions in order to be successful over long periods of time. Thus ***the growth forms of plants** strongly reflect their environment in ways that can be compared around the world. Furthermore, by providing threedimensional structure, by modifying physical conditions near the ground, and by providing food, dominant plants strongly influence the organisms living there.

Figure 53.13 Global Distribution of Terrestrial Biomes The distribution of terrestrial biomes is determined primarily by annual patterns of temperature and precipitation.

Q: Does the Northern or Southern Hemisphere have a greater number of biomes? What do you think might determine this difference?

Activity 53.1 **Biomes** www.Life11e.com/ac53.1

Activity 53.2 **Aquatic Biomes** www.Life11e.com/ac53.2

In the following pages we briefly describe seven terrestrial biomes (a subset of those shown in [Figure 53.13](#)). For each, a plot of the seasonal patterns of temperature and precipitation — known as a **Walter climate diagram** — is included. Devised by the German biogeographers Heinrich Walter and Helmut Lieth, this graphic technique plots temperature and precipitation data in a simple way that visualizes a “growing season”—those months when average temperatures are above freezing (0°C) and when average precipitation is sufficient for plant growth. Walter climate diagrams are predicated on the “rule of thumb” that plant growth requires temperatures above 0°C and at least 2 mm of precipitation for each 1°C rise in temperature above 0°C . They have two y-axis scales, one for temperature and one for precipitation; these axes align 0 mm of precipitation with 0°C of temperature. The x axis shows 12 months, with the summer solstice placed in the center of the axis.

Walter climate diagram A graphic technique that plots temperature and precipitation data to visualize a growing season for plants (those months when average temperatures are above freezing and average precipitation is sufficient for plant growth).

TROPICAL RAINFOREST

The tropical rainforest biome is found in equatorial regions where rainfall and temperatures are

high year round. With no season unsuitable for growth, it is the most productive and species-rich of all biomes. In some areas, there are up to 500 species of trees per square kilometer. Although historically these forests covered 12 percent of Earth's surface, and are now reduced through deforestation, they are home to more than half of all known species. These forests are home to many epiphytes—plants that grow on other plants, deriving their nutrients and moisture from air and water rather than soil.

Tropical rainforests provide humans with a range of products, including fruits, nuts, medicines, fuel, pulp, and furniture wood. Rainforests, however, are currently being cut down or converted to agriculture at a rate of almost 1 percent per year. In some cases, rainforests are recovering but the soils are often nutrient-poor, hindering regrowth.

DESERT

The desert biome is concentrated in two belts, centered around 30 °N and 30 °S latitude (where warm, dry air sinks under high atmospheric pressure; see [Figures 53.4](#) and [53.5](#)). The driest of these regions, where rains rarely fall, are far from the oceans, as in the center of Australia and the middle of the Sahara in Africa.

Desert plants have several structural and physiological adaptations that help them conserve water, as described in Key Concept

Humans have used deserts for livestock grazing and agriculture for centuries. Deserts can be irrigated from deep wells or distant mountains, but such efforts typically fail as a result of salinization, the buildup of salts from the evaporation of irrigation water.

TEMPERATE GRASSLAND

Temperate grasslands are found in many parts of the world, all of which are relatively dry for much of the year. Most grasslands, such as the pampas of Argentina, the veldt of South Africa, and the Great Plains of North America, have hot summers and relatively cold winters. In some grasslands, most of the precipitation falls in winter (as in California grasslands); in others, the majority falls in summer (as in the Great Plains and the Russian steppe).

Grassland vegetation is structurally simple but rich in species of perennial grasses and forbs (herbaceous plants). Grassland plants support herds of large grazing mammals and are adapted to grazing and to fire. They store much of their energy underground and resprout quickly after being burned or grazed. There are comparatively few trees in temperate grasslands because trees cannot survive the periodic fires or the dry conditions.

The topsoil of grasslands is usually rich and deep, and thus exceptionally well suited to growing crops such as corn and wheat. As a consequence, most of the world's temperate grasslands have been turned over to agriculture and no longer exist in their natural state.

TEMPERATE DECIDUOUS FOREST

The temperate deciduous forest biome is found in eastern North America, eastern Asia, and Europe. Temperatures in these regions fluctuate dramatically between summer and winter, although precipitation is fairly evenly distributed throughout the year. The deciduous trees that dominate these forests lose their leaves during the cold winters and produce new leaves during the warm, moist summers.

The temperate deciduous forests have many more species than boreal forest ecosystems.

Those with the highest species richness occur in the southern Appalachian Mountains of the United States and eastern China and Japan—areas that were not covered by glaciers during the Pleistocene. Many plant genera are shared among the three geographically separate regions where this biome is found.

Although many animals are permanent residents of deciduous forests, some (including many birds) migrate to find food resources and escape the winter cold. Others that remain through the winter hibernate (see [Key Concept 39.5](#)), often in underground burrows. Many insects pass the winter in a state of diapause (suspended development), the onset of which is triggered by the decreasing hours of daylight—a reliable predictor of winter.

BOREAL FOREST AND TEMPERATE EVERGREEN FOREST

The boreal forest biome (also known as taiga) occurs just above 50 °N but below Arctic tundra, and at elevations below alpine tundra on temperate-zone mountains. Winters in the boreal forest are long and very cold; summers are short, although often relatively warm. The boreal forests of the Northern Hemisphere are dominated by coniferous trees such as spruces and firs. The short summers favor evergreen leaves, which are ready to photosynthesize as soon as temperatures warm. In winter, downward-drooping limbs allow the trees to shed snow easily.

The dominant mammals of the boreal forest, such as moose and hares, eat leaves, but the seeds in conifer cones support a variety of rodents, birds, and insects. Many small mammals hibernate in winter, but voles, lemmings, and mice remain active under the snowpack, serving as food for predators such as foxes and owls.

The temperate evergreen forest biome occurs along the coasts of continents in both hemispheres at middle to high latitudes, where winters are mild and wet and summers are cool and dry. In the Northern Hemisphere, the dominant trees in temperate evergreen forests are conifers, some of which are the world's most massive tree species (including the giant sequoia

and coast redwood). In the Southern Hemisphere, the dominant trees are southern beeches (*Nothofagus*), some of which are evergreen.

TUNDRA

The tundra biome is found at high latitudes (above 65 °) characterized by low temperatures and a short growing season. This biome is underlain by permafrost—soil permeated with permanently frozen water. The top few centimeters of the soil thaw during the short summers, when the sun may be above the horizon 24 hours a day. Thus even though there is little precipitation near the poles, the soil in lowland Arctic tundra is wet because water cannot drain through the permafrost. As a result, trees cannot grow in the tundra biome because their roots cannot penetrate the permafrost. Instead, the tundra biome is characterized by sedges, forbs, grasses, and low-growing shrubs such as heaths, willows, and birches. Lichens and mosses are also important vegetation.

Tundra plants have several structural and physiological adaptations that help them conserve heat, as described in [Key Concept 38.3](#). Most animals are either summer migrants or are dormant for much of the year. Resident birds and mammals, such as the willow ptarmigan (*Lagopus lagopus*) and Arctic fox (*Vulpes lagopus*), have thick fur or feathers that may change color with the seasons, from brown in summer to white in winter.

TEMPERATE DECIDUOUS FOREST

Layers of autumn foliage in a deciduous forest on Miyajima Island, Japan.

North American deciduous forests are a common home for the black bear (*Ursus americanus*).

Wellsboro, Pennsylvania, USA
41°N

Average annual temperature 7.6°C
Total annual precipitation 848 mm

The deciduous forest biome is home to the spotted salamander (*Ambystoma maculatum*) who breeds in vernal pools in Massachusetts, USA.

Biogeographic regions reflect evolutionary isolation

Climate interacts with local abiotic features to influence where and how organisms live, but these are not the only factors determining where organisms are found. Evolutionary history—

where and when species originated and diverged—is key to determining their biogeography.

Until European naturalists traveled the globe in the nineteenth century, they had no way of knowing how organisms were distributed in other parts of the world. Alfred Russel Wallace, who along with Charles Darwin advanced the idea that natural selection could account for the evolution of life on Earth (see [Key Concept 20.1](#)), was one of those global travelers. Wallace spent seven years in the Malay Archipelago, where he noticed some remarkable patterns in the distributions of species. For example, he described the dramatically different species that inhabited the adjacent islands of Bali and Lombok. He pointed out that the differences could not be explained by the physical environment, because Bali and Lombok are only 24 kilometers apart.

Wallace saw that, based on the distributions of plant and animal species, he could draw a line that divided the Malay Archipelago into two distinct halves. He correctly deduced that the dramatic differences in flora and fauna were related to the depth of the channel separating Bali and Lombok. This channel is so deep that it would have remained full of water, and thus would have been a barrier to the movement of terrestrial animals, even during the glaciations of the Pleistocene epoch, when sea level dropped more than 100 meters and Bali and the islands to the west were connected to the Asian mainland.

With these insights, Wallace established the conceptual foundations of biogeography. In *The Geographical Distribution of Animals*, published in 1876, he detailed the factors known at the time that influence the distributions of animals, including past glaciation, land bridges, deep ocean channels, and mountain ranges. He earned some measure of scientific immortality in that the Malay discontinuity that first piqued his curiosity is known to this day as “Wallace’s line” (see

Figure 53.14 Earth's Biogeographic Regions Wallace identified six major biogeographic regions that are separated by climatic, topographic, or aquatic barriers to dispersal that cause their biotas to differ strikingly from one another. The red arrows on the map show the time (in millions of years) since land masses came together. Black arrows show the time since land masses separated. These areas roughly correspond to Earth's major tectonic plates.

Q: As land masses separated, would you expect speciation to increase? Explain.

Activity 53.3 Major Biogeographic Regions www.Life11e.com/ac53.3

The biotas of different parts of the world differ enough to allow us to divide Earth into many continental-scale areas called **biogeographic regions**, each containing characteristic assemblages of species. The boundaries of the biogeographic regions in [Figure 53.14](#) were originally proposed by Wallace, and represent assemblages of species that change dramatically, often over short distances. A major process controlling the formation of these biogeographic regions is ***continental drift**. For example, we now know that over the course of the Triassic and Jurassic periods, the supercontinent Pangaea separated into two great land masses, Laurasia and Gondwana (see [Figure 24.14](#)), which subsequently separated into the continents we know today. After the land masses broke up, the descendants of the organisms widely distributed across Pangaea evolved independently, forming new species and new species assemblages. The legacy of these continental movements can be found in several existing taxonomic groups and in the fossil record. For example, the modern southern beeches—trees of the genus *Nothofagus*—are found in both the Neotropical and the Australasian biogeographic regions. Evidence of fossilized *Nothofagus* pollen from 55 to 34 million years ago has also been found in Australia, New Zealand, western Antarctica, and South America, suggesting that beeches originated in Gondwana during the Cretaceous period and were geographically separated by the breakup of that land mass 100 million years ago (see [Figure 53.14](#)).

biogeographic region Distinct regions of biota characterized by different species that occur at the continental-scale. (Contrast with biome.)

The evolutionary separation of species can be attributed to two basic processes, vicariance and dispersal. **Vicariance** occurs when a physical barrier prevents dispersal and divides a species into two or more discontinuous populations. Dispersal occurs when the members of a species cross an existing barrier and establish a new population elsewhere.

vicariance (vye care' ee uns) [L. *vicus*: change] The evolutionary separation of species due to a barrier that results in the geographic isolation of species that once were connected to one another.

Given that the processes of vicariance and dispersal both influence distribution patterns, how can biogeographers determine the role of each process when reconstructing the evolutionary history of a particular species? As you saw in [Chapter 21](#), taxonomists have developed powerful molecular methods of reconstructing the phylogenetic relationships among organisms that can be used to understand how organisms came to occupy their present-day distributions. Phylogenetic trees can be used to discover whether the distribution of an ancestral species was influenced by a vicariant event, such as continental drift or a change in sea level, or is simply the result of a dispersal event.

Media Clip 53.1 Rafting to Madagascar www.Life11e.com/mc53.1

Diversity varies with latitude and longitude

About 200 years ago, the German explorer and naturalist Alexander von Humboldt spent 5 years traveling around Latin America. He remarked in the account of his voyages that “the nearer we approach the tropics, the greater the increase in the variety of structure, grace of form, and mixture of colors, as also in perpetual youth and vigour of organic life.” Humboldt and other nineteenth-century scientific explorers such as Wallace and Darwin became keenly aware of this pattern as they collected thousands of species in the tropics and compared them with their more meager collections from Europe. As more observations and collections have been made over the last 200 years, the latitudinal gradient in species diversity has been established for a wide variety of taxa, including some groups of birds, mammals, flowering plants, and insects such as swallowtail butterflies ([Figure 53.15A](#)). Significant variation in species diversity is also seen with longitude, but the number of species depends largely on the longitudes chosen.

Figure 53.15 Latitudinal Gradients in Diversity (A) Among swallowtail butterflies (Papilionidae), species richness decreases with latitude both north and south of the equator. **(B)** Seabirds, by contrast, show a positive relationship between species diversity and latitude: the number of seabird species increases at higher latitudes.

There are intriguing exceptions to the classic latitudinal patterns of species diversity just described. Some taxa show a positive relationship between species number and latitude ([Figure 53.15B](#)). That is, among some taxa—for example, seabirds—species number increases at higher latitudes. This pattern of seabird diversity correlates with marine ***net primary productivity**, which is substantially higher in temperate and polar oceans than in the tropics.

We consider productivity differences along with other explanations of latitudinal gradients in diversity in the next section.

Geographic variation in diversity is explained by multiple factors

Although most ecologists agree that latitudinal gradients in diversity exist, there is much less consensus as to why they exist. Dozens of hypotheses have been proposed to explain these patterns, but they are hard to evaluate—in part because there are multiple and confounding differences in such factors as geographic area, climate, and productivity with latitude. More

important, because these factors operate at large spatial scales and over evolutionary time, it is impossible to conduct experiments to isolate the factors and separate correlation from causation.

Here we present three well-known hypotheses that have been advanced to account for latitudinal gradients in diversity. Corroborative evidence can be found for each of these hypotheses, varying with taxon, locality, and scale, which suggests that none of these hypotheses is mutually exclusive. Multiple factors, working at multiple spatial scales, are likely responsible for common biogeographic patterns.

SPECIES DIVERSIFICATION RATE

This hypothesis proposes that in the tropics the rate of speciation is higher and the rate of extinctions is lower, resulting in an overall higher species diversity than in temperate or polar regions. Two factors could account for a higher speciation rate in the tropics: a larger geographic area (this is the widest part of the planet, so it encompasses the greatest amount of area) and a warm and stable climate. The rationale is that a larger geographic area with a consistent climate should promote speciation because species will have larger geographic ranges, giving them a greater chance of reproductive isolation (see [Key Concept 22.2](#)). In addition, these large and stable areas should reduce extinctions. The net result should be an increase in the number of species in the tropics.

SPECIES DIVERSIFICATION TIME

This hypothesis proposes that the amount of time over which speciation has taken place is greatest in the tropics — in other words, that the tropics have a longer evolutionary history than temperate or polar regions. First championed by Wallace in 1878, this hypothesis proposes that tropical regions, because they are more climatically stable over time, have more time to diversify than temperate or polar regions, where severe climate conditions (such as ice ages) could have decreased speciation and increased extinction. Thus even if the rates of speciation and extinction are the same worldwide, the tropics should have accumulated more species over time simply because of the lack of dramatic changes in climate.

PRODUCTIVITY

This hypothesis proposes that species diversification is promoted by higher productivity, which allows species more resources and thus decreased risk of species extinction due to competition. The productivity hypothesis might explain the positive relationship between seabird diversity and increasing latitude, given that ocean productivity is generally higher at temperate and polar latitudes. As you will see in [Chapter 56](#), the role of productivity can more easily be explored at smaller spatial scales, where experiments can give us a better idea of its role in promoting species diversity.

53.4 recap

Biogeographic patterns are interconnected across a hierarchy of scales ranging from global to local. Three strong biogeographic patterns can be seen: (1) biomes or groupings of ecologically similar organisms are shaped by the environment, (2) diversity varies from continent to continent, forming biogeographic regions, and (3) diversity varies with latitude.

learning outcomes

You should be able to:

- Describe the principle characteristics of each of the seven major biomes featured in this section, including climate, latitude and/or continent(s), and representative plants and animals.

- Use the observations and insights of Alfred Russel Wallace to explain how biogeography might influence the distribution of plants and animals.
 - Compare and contrast the hypotheses posed for latitudinal patterns of species diversity, including species diversification rate, species diversification time, and productivity, giving examples of situations that could be used to explain each one.
-

1. Describe the information used to characterize biomes. What are the differences and similarities between the rainforest biome and the temperate evergreen forest biome?
2. Refer to [Figure 53.14](#). Why did Wallace's line help explain what controls the formation of biogeographic regions?
3. Over Earth's history, ice sheets extended into temperate latitudes. Does this fact better support the species diversification rate or the species diversification time hypothesis proposed to explain latitudinal variation in diversity? Explain.

As you have seen, an important aspect of biogeography is the relationship between diversity and geographic area. We have considered this relationship at global scales. We turn now to smaller regional scales, to understand in more detail the importance of geographic area to patterns of biogeography.

***connect the concepts** Plants growing in a particular type of environment (e.g., the desert) may display similar growth forms (e.g., succulence). See [Key Concept 38.3](#).

***connect the concepts** Earth's land masses have undergone continental drift over the millennia as a result of plate tectonics, shaping the major patterns of biogeography today and in the past. See [Key Concepts 24.2](#) and [24.3](#).

***connect the concepts** Net primary production (NPP) is the amount of biomass incorporated into the tissues of primary producers and is the base of all food chains. Oceanic NPP is highest at mid-latitudes. See [Key Concept 57.2](#).

53.5 Geographic Area and Humans Affect Regional Species Diversity

Biogeographers have repeatedly documented what is termed the [species-area relationship](#), in which species diversity increases with increasing area. The relationship has most often been measured for islands or islandlike habitats—any isolated area surrounded by a “sea” of dissimilar habitat. In addition to showing a pattern of increasing species diversity with increasing area, islands also show a pattern of decreasing species number with distance from the source of those species, or the species pool ([Figure 53.16](#)). How do island area and distance act together to produce species-area relationships?

species–area relationship The relationship between the size of an area and the numbers of species it supports.

Figure 53.16 The Species-Area Relationship E. O. Wilson and Robert MacArthur plotted the number of species of birds against the size and distance of islands from New Guinea. Larger and closer islands consistently contained more species, a fact that these scientists incorporated in their theory of island biogeography.

focus your learning

The species-area relationship is explained by the theory of island biogeography, which considers the balance between species immigration and extinction.

As humans fragment Earth's biomes through agriculture, deforestation, and urbanization, remaining habitats become more isolated, or islandlike.

The biologist Edward O. Wilson was struck by the species-area relationship from his research on ant biogeography and was looking for explanations. He teamed up with Robert MacArthur, a gifted mathematical ecologist, to develop the [theory of island biogeography](#) to explain this pattern. They based their theory on just two processes: the immigration of new species to an island and the extinction of species already present on that island ([Figure 53.17](#)). The premise of island biogeography is that the number of species on an island represents a balance between the rate at which species immigrate to and colonize the island and the rate at which resident species become locally extinct.

theory of island biogeography A theory proposing that the number of species on an island (or in another geographically defined and isolated area) represents a balance, or equilibrium, between the rate at which species immigrate to the island and the rate at which resident species go extinct.

Figure 53.17 The Equilibrium Theory of Island Biogeography MacArthur and Wilson's theory emphasized the balance between species immigration rates and species extinction rates for islands of different sizes and at different distances from a source of colonizing species.

Activity 53.4 Biogeography Simulation www.Life11e.com/ac53.4

The rate of immigration is determined in part by the number of species in the regional species pool. In the case of oceanic islands, the species pool comprises all the species on the nearest mainland location. Not all species that reach the island will persist there, however. The more species there are on an island, the greater the likelihood that some will go extinct, either due to chance or the inability to coexist with other species on the island. The number of species that will be sustained on any particular island is determined by the balance of the immigration rate and the extinction rate for that island. Even though species will come and go over time (i.e., immigrate and become extinct), that turnover will always result in some equilibrium number of species, assuming a constant species pool and natural extinction events.

The actual number of species on an island will ultimately depend on two factors:

- . *The size (area) of the island.* The smaller the island, the fewer resources it provides, the greater the potential for competition, and the higher the extinction rate will be (see [Figure 53.17](#)). Larger islands provide greater resources and can sustain larger populations (which tend to have lower extinction rates than small populations).
- . *Distance of the island from the species pool.* The farther the island is from the source of immigrants, the lower the immigration rate—the rate at which new species arrive—will be (see [Figure 53.17](#)).

Between 1966 and 1969, Wilson and his student Daniel Simberloff conducted an experiment to test the theory of island biogeography, using arthropods living on mangrove islands in the Florida Keys. You can view this experiment and the results online.

Animation 53.3 Island Biogeography in the Florida Keys www.Life11e.com/a53.3

Humans exert a powerful influence on biogeographic patterns

The theory of island biogeography has provided surprising insight into the role human's play in regional biogeographic patterns. As you saw in [Key Concepts 53.3](#) and [53.4](#), Earth's biomes are becoming smaller and more fragmented by local- and regional-scale forces such as agriculture, deforestation, and urbanization. They are being transformed into islandlike habitats—isolated patches of suitable habitat such as parks or forest fragments, surrounded by extensive areas of unsuitable habitat similar to the cattle pastures of Amazonia described at the opening of this chapter.

The fragmentation of the Amazon rainforest led Thomas Lovejoy and his colleagues to initiate, in 1979, one of the largest and longest-running ecological experiments ever conducted to investigate the effects of tropical forest fragmentation on species diversity (**[Investigating Life: The Largest Experiment on Earth](#)**). The Biological Dynamics of Forest Fragments Project (BDFFP) took advantage of an existing Brazilian law that required landowners who cut rainforest to leave half of it untouched. Lovejoy was able to survey the species diversity in different-sized fragments (either 1, 10, or 100 hectares [ha] in size surrounded by deforested land). Among a number of results, his group found that, after more than 30 years of isolation, even the largest deforested fragments surveyed (100 ha) had lost half of their bird species diversity. The researchers were also surprised by two additional findings. First, even minimal distances of 80 meters between fragments resulted in strong avoidance of the clearings, and thus isolation, by birds, insects, and tree-dwelling mammals that lived in the fragments. Second, the fragmentation exposed species within a fragment to a variety of potential hazards, including extreme heat, fires, hunting, predators, diseases, and invasive species. These so-called [edge effects](#) not only reduce the immigration rate from one fragment to another, thus contributing to a smaller species pool, but they effectively reduce the size of the fragment, thus increasing the extinction rate, by making the edge of the fragment much less hospitable habitat.

experiment

Original Paper: Ferraz, G. et al. 2003. Rates of species loss from Amazonian forest fragments. *Proceedings of the National Academy of Sciences USA* 100: 14069–14073.

Thomas Lovejoy and his colleagues asked what was the minimum area needed to maintain species diversity in the rainforest fragments created by logging near Manaus, Brazil. They conducted an experiment, starting in 1979, that took advantage of an existing Brazilian law that required landowners who cut rainforest to leave half of it untouched. In 2003, Ferraz and colleagues reported on one particular aspect of the experiment: the number of forest understory birds living in different-sized forest fragments surrounded by deforested land.

HYPOTHESIS ▶ The number of understory bird species will decline faster after the isolation of the fragment, and in smaller rainforest fragments compared with larger rainforest fragments.

METHOD

1. Starting in 1979, fragments of three sizes (1, 10, and 100 hectares) were established 80 kilometers north of Manaus. The fragments were separated from continuous forest by at least 100 meters of cleared land.

investigatinglife work with the data follows on next page.

2. Birds were captured in mist nests placed in the fragments prior to deforestation and then for 12 years after fragment establishment. The mist nets were placed in roughly the same locations throughout the study.
3. Each newly captured bird was recorded for species, given an individually numbered band, and released back into the rainforest from which it was caught.
4. The data gathered were used in species-loss curves for each fragment, and a scaling factor (i.e., a number that scales, or multiplies, by some quantity) was estimated to determine the time it takes to lose half of the bird species (t_{50}) in fragments of different sizes.

RESULTS

The average initial number of species was 83 for the 1-hectare fragment, 92 for the 10-hectare fragment, and 113 for the 100-hectare fragment. Despite finding a total of 164 understory bird species in the fragments over the course of 13 years, there was a significant drop in the number of species over time. The t_{50} was shortest in the 1-hectare fragments and longest in the 100-hectare fragments. Fragments of 100 hectares were predicted to lose half of their species in 12 years.

CONCLUSION ▶ The number of understory bird species declined after the fragmentation of tropical rainforest habitat by deforestation. Smaller rainforest fragments lost species faster than larger forest fragments. Even the largest fragments were predicted to lose half of their bird species in 12 years.

Animation 53.4 Edge Effects
www.Life11e.com/a53.4

work with the data

The data in the graph shown in the experiment can be used to calculate a scaling factor for the time it takes to lose half of the bird species within a fragment. The scaling factor shows that to increase the t_{50} (i.e., the time it takes fragments to lose half their species) by 10-fold, fragment area would need to increase 1,000-fold. Here you will use this scaling factor and other data provided in the graph to determine the area needed for the conservation of understory birds in the Amazon forests outside Manaus, Brazil.

QUESTIONS

1. Graph the initial numbers of bird species by the size of the fragment area. Do these fragments follow the species–area relationship?
2. Suppose you are consulting for the Brazilian government on the

conservation of rainforests near Manaus. Assuming that the t_{50} for 1 hectare is 5 years, what is the minimum size that a rainforest fragment in the Manaus area needs to be to ensure that half of the bird species remain 50 years after the deforestation event that isolated them? How about a century after deforestation?

3. Suppose it takes 100 years for rainforests to fully recover after a deforestation event in the Manaus region. Given that the average size of a rainforest fragment in this area is no bigger than 1,000 hectares, will the number of species decline by half before the recovery of rainforest occurs around the largest fragments?

A similar **work with the data** exercise may be assigned in **LaunchPad**.

53.5 recap

Species-area relationships, in which species diversity increases with increasing area, have been shown for islands and islandlike habitats. Smaller islands have higher extinction rates and lower immigration rates compared with larger islands. Earth's biomes are becoming smaller and more fragmented by human activities, leading to lower diversity in the remaining habitats.

learning outcomes

You should be able to:

- Explain the species-area relationship and use a conceptual model to describe it.
- Describe specific ways in which habitat fragmentation negatively affects species diversity, using the Amazon rainforest as an example.

1. Using [Figure 53.17](#), explain how and why the small and far islands have lower species numbers than the large and near islands.
2. Why is habitat fragmentation by human activities threatening species diversity? Besides ceasing the activity altogether, what can be done to reduce this threat?

▶ investigating life

QA How do geographic area and isolation affect the biogeography of life on Earth?

At the opening of the chapter, we asked how geographic area and isolation might affect the biogeography of life on Earth. You have seen that this question is highly relevant at different spatial scales—from whole continents to small islands—and also over different time scales—from millions of years to months. Because the spatial and temporal scales at which biogeographic patterns manifest themselves are so wide and interconnected, it can be hard to test theories of biogeography with experiments that are large and long enough to be meaningful. The Biological Dynamics of Forest Fragments Project (BDFFP), an experiment conducted in the most species-rich region of the world, and at arguably the largest scale ever attempted, offers support for theories proposed nearly 200 years ago by explorers such as Humboldt, Wallace, and Darwin, who hypothesized that the distribution of species on Earth is highly influenced by the geographic area and isolation those species have experienced. The question remains, in the case of the Amazon Basin, whether species will ultimately adapt to the changing biogeographic landscape or become a casualty of an extinction event that would be unrivaled in human history.

Future directions

One of the major findings of the BDFFP is the importance of connectivity in maintaining species diversity. Management and permitting of forest clearing are focusing on creative ways to connect forest fragments by taking advantage of existing landscape features to increase connectivity of disturbed habitat. For example, in Amazonia strong laws exist to prohibit clearing forest along rivers and steep slopes, providing strips of land that can serve to connect fragments around newly cleared land.

► 53.1 Ecology Is the Study of the Interrelationships among Organisms and the Environment

- **Ecology** differs from **environmentalism**, which involves the use of ecological knowledge to inform our stewardship of natural resources.
- Ecologists have a use-inspired focus to their research, motivated by a desire to improve Earth's ecological problems.
- Ecology is studied at multiple levels of organization, ranging from individuals to the biosphere. **Review Figure 53.1**

► 53.2 Global Climate Is a Fundamental Component of the Physical Environment

- Climate and weather both refer to atmospheric conditions, but climate represents conditions over years to millennia whereas weather represents conditions over days to weeks.
- Solar radiation drives global climate. About 30 percent of the solar radiation that hits Earth is reflected back to space. The rest is absorbed either by the atmosphere (20%) or by Earth's surface (50%). Greenhouse gases in the atmosphere allow sunlight into Earth's atmosphere but trap heat radiating back out toward space. **Review Figure 53.2, Animation 53.1**
- Latitudinal differences in solar energy input drive patterns of atmospheric circulation. **Review Figures 53.3, 53.5**
- The interaction of Earth's rotation and north-south air mass movements generate prevailing winds, which in turn drive ocean currents. **Review Figures 53.6, 53.7**
- The seasons are a consequence of Earth's tilt and orbit around the sun. **Review Figure 53.8**

► 53.3 Topography, Vegetation, and Humans Modify the Physical Environment

- On land, Earth's topography creates rain shadows and temperature inversions, producing variation in temperature and precipitation **Review Figure 53.9A and B, Animation 53.2**
- The topography of the ocean floor produces variation in water depth, which affects light penetration and water temperature, pressure, and movement, creating aquatic zones and ocean upwelling. **Review Figure 53.9C and D**
- Vegetation, especially forests, affects climate through the process of evapotranspiration. **Review Figure 53.10**

► 53.4 Biogeography Is the Study of How Organisms Are Distributed on Earth

- Patterns of biogeography are interconnected across a hierarchy of scales, ranging from global to regional to landscape to local. **Review Focus: Key Figure 53.12**
- Biomes are groups of ecologically similar dominant plants that are shaped by patterns of

temperature and precipitation. Review [Figure 53.13](#), [Activities 53.1, 53.2](#)

- Earth's diversity varies from continent to continent, forming biogeographic regions and reflecting evolutionary isolation as a consequence of Earth's geological history. Review [Figure 53.14](#), [Activity 53.3](#)

Original Paper: Holbrook, S. J. et al. 2015. Reef fishes in biodiversity hotspots are at greatest risk from loss of coral species. *PLoS ONE* 10: e0124054.

As you learned in [Chapter 1](#), climate change and human activities pose substantial threats to tropical coral reefs. These species-rich ecosystems make up less than 1 percent of the coastal ocean but contain more than 25 percent of all marine species.

A group of researchers studied the species diversity of reef fishes, which depend on coral reefs for food and habitat. They found a positive relationship between fish species diversity and coral species diversity. Coral reefs support a variety of fish species, including both generalists and specialists, but as coral diversity increases, the number of fish specialists—those that depend on one or a very few coral species—also increases. The researchers hypothesized that if reefs were degraded, locations with the highest fish diversity would suffer the greatest proportional declines, because of the loss of certain fish species that specialize on certain coral habitats. They reasoned that if coral species disappeared, their associated fish species would also disappear.

The researchers set up identical experiments in three geographic locations across the Indo-Pacific, as represented in [Figure A](#). Kimbe Bay, in Papua New Guinea (PNG), has the greatest number of fish species (approximately 1,600 species). Moorea Island, in French Polynesia, has the lowest number of fish species. Lizard Island, in the Great Barrier Reef, has an intermediate number of fish species, 10-15 percent lower than PNG.

Figure A

Figure B

At each of the three reef sites across the Indo-Pacific, the researchers experimentally manipulated three levels of coral diversity: high diversity (six coral species), medium diversity (three coral species), and low diversity (one coral species) within separate plots. They used the same coral species in all the plots and counted fish species four times during a 12-month period.

Results for the final count are shown in **Figure B**. Researchers calculated an “index of sensitivity” to evaluate the relationship between the number of coral species in the experimental plots and the number of fish species that inhabited the plots. The zero line indicates no difference in fish species diversity; positive values indicate proportionally greater decreases in fish species present with declining coral species in the plots. That is, fish species from the Kimbe Bay site were more sensitive to changes in the number of coral species than were fish species from lower diversity areas, and they were more likely to suffer local extinctions.

Questions

1. What do the results of this experiment suggest about the relationship between the number of fish species and the species diversity of corals on the reefs they inhabit? Explain how this insight might be used to preserve or maintain coral reef ecosystems currently under threat.
2. Based on the map, at which sites do you think the species diversity of corals and fish would be most affected by the process of dispersal, or immigration, of species to the site(s), and which would be least affected?
3. What major factors could have resulted in the development of the high coral reef species diversity at the Kimbe Bay site? Why do the other sites have lower species diversity?
4. As climate change progresses, ocean waters are becoming both warmer and more acidic, causing the decline in corals worldwide. What effect would these changes in coral reef species diversity likely have on fish species diversity in the three areas? Explain possible reasons for these changes and what variations might occur in each area.

[54.4 Population Biology Can Be Used in Conserving and Managing Populations](#)

Earth's Human Carrying Capacity

In 1798 Thomas Robert Malthus, in his *Essay on the Principle of Population*, pointed out that the human population was growing exponentially but its food supply was not, and argued that at some point, famine and death would be the ultimate fate of the human race. Malthus could not have anticipated the technological innovations over the next 200 years that would greatly enhance our food production and health care. Today, however, the size of the human population is once again a serious concern as we confront the effects of our contributions to climate change, pollution, habitat destruction, and species extinctions.

For thousands of years, Earth's capacity to support human populations was low because of the relative inefficiency with which we could obtain food and water. The development of social systems and communication, the domestication of plants and animals, ever-increasing crop and livestock yields due to ongoing technological advances, and our increasing proficiency at managing diseases all contributed to unprecedented growth of the human population. It took more than 200,000 years for the human population to reach 1 billion people, which happened in the early nineteenth century. Today, a mere 200 years later, the planet is home to roughly 7.4 billion human beings.

Many believe that human populations will (if they have not already) reach some maximum size (known as the population's carrying capacity) above which continued population growth is unsustainable. Food production is critical to human population growth and currently uses large amounts of land, water, fertilizers, and energy. Housing and quality health care require advances in infrastructure and drug production, and these too are highly energy-intensive. In addition, if Earth's ecosystems continue to be degraded, human populations may experience a general breakdown of Earth's life support systems.

Luckily, population growth rate has slowed from its high after World War II, but with a base of 7.4 billion, even minimal population growth rate means millions more individuals each year. As you will see later in the chapter, population biologists have used census data and standard population growth models to predict human population sizes into the future.

What is the human population growth projected to be in the next century, and how will that affect population size?

Media Clip 54.1 World Population Growth www.Life11e.com/mc54.1

54.1 Populations Show Dynamic Variation in Size over Space and Time

Species, whether they are humans, yeast, or giant redwood trees, are divided into groups of individuals, or populations. A **population** is a group of individuals of the same species within a given area that have the potential to interbreed and interact with one another. As you might expect, populations vary in their **population size**—the numbers of individuals within a population. Well before ecology became a distinct biological discipline, humans were interested in **population dynamics**, or the patterns and processes of population change over space and time. Growing crops, raising livestock, and controlling pests all involve paying attention to population dynamics. To this day, game wardens, park managers, and conservation biologists aim to maintain stable populations of fish, wildlife, and threatened or endangered species in the face of change. Here we consider population dynamics in more detail.

population (1) In biology, any group of organisms coexisting at the same time and in the same place and capable of interbreeding with one another. (2) In statistics, a study group of interest.

population size The total number of individuals in a population.

population dynamics The patterns and processes of change in populations over space and time.

focus your learning

Populations are dynamic; they vary in size, range, and dispersion patterns, and they vary over time.

Three main factors affect population dynamics: the physical environment, biological interactions, and dispersal.

Ecologists estimate population size and extent using a variety of techniques.

Part of the dynamism that populations show is a consequence of their distribution across the landscape (**Figure 54.1A**). For example, distribution maps of the herbaceous perennial *Clematis fremontii* show that it is patchily distributed across Missouri, Kansas and Nebraska. Here populations are restricted to dry, rocky meadows formed on particular limestone outcrops within the region. Populations, such as those of *Clematis*, rarely occur in isolation from one another but are usually connected through dispersal. **Dispersal** is simply the movement of individuals into (**immigration**) or out of (**emigration**) an existing population. A group of geographically isolated populations linked together by dispersal is known as a **metapopulation**. For example, a cluster of meadows might be considered a metapopulation if *Clematis* seeds from one meadow had the potential to disperse to another meadow. At larger spatial scales, the entire **geographic range** or distribution of a species might consist of one or multiple metapopulations, depending on the extent of the area occupied by a species.

Figure 54.1 Many Populations Have Patchy Distributions The distribution and abundance of the herbaceous perennial *Clematis fremontii* are patchy over different spatial scales. **(A)** Populations occur within limestone meadows. A group of populations makes up a metapopulation, and multiple metapopulations make up the geographic range (in this case, Missouri, Kansas, and Nebraska). **(B)** Individuals within a population show one of three different dispersion patterns.

dispersal Movement of individuals into (immigration) or out of (emigration) an existing population.

immigration Dispersal of individuals into an existing population. (Contrast with emigration.)

emigration Dispersal of individuals out of an existing population. (Contrast with immigration.)

metapopulation A group of geographically isolated populations linked together by dispersal.

geographic range The entire region within which a species occurs.

Species differ greatly in their geographic ranges—they can be as wide ranging as the acorn barnacle *Semibalanus balanoides*, which extends along both North American coasts and the European Atlantic coast. However, even though dispersal links populations, most species have fairly restrictive geographic ranges such as we see for *Clematis*. We call such species **endemic** because they occur in one particular location and nowhere else on Earth. Thus *Clematis* can be said to be endemic to the central United States because its geographic range is restricted to that region.

endemic (en dem' ik) [Gk. *endemos*: native] A species that occurs in a particular location and nowhere else on Earth.

Within a population, the spatial arrangement of individuals may vary in what are known as **dispersion patterns**. Ecologists recognize three basic dispersion patterns: (1) **regular** (or **uniform**) **dispersion**, characterized by evenly spaced individuals, (2) **random dispersion**, in which individuals are randomly spaced, and (3) **clumped dispersion**, in which individuals tend to be clustered in groups (**Figure 54.1B**). As we will consider later in this section, multiple processes such as resource availability, species interactions, and dispersal can shape the dispersion patterns we see in nature.

dispersion patterns The spatial arrangement of individuals in space within a population. (See regular, random, and clumped patterns.)

regular (uniform) dispersion The spatial arrangement of individuals within a population, characterized by evenly spaced individuals. (Compare with clumped dispersion, random dispersion.)

random dispersion The spatial arrangement of individuals within a population, characterized by random spatial patterns. (Compare with clumped dispersion, regular (uniform) dispersion.)

clumped dispersion The spatial arrangement of individuals within a population, characterized by clumped spatial patterns. (Compare with random dispersion, regular (uniform) dispersion.)

Populations can vary over time as well. For example, some populations may show “boom and bust” cycles, such as we see for bacteria, yeast, and phytoplankton, in which the population size can vary over just a few minutes to days. Species that show wide fluctuations in population size tend to have reproductive strategies that allow them to respond rapidly to changing resources. They may also have predators that are able to take advantage of these outbursts in growth. For example, aphids engage in parthenogenetic reproduction—a type of asexual reproduction resulting in genetically identical individuals (see [Key Concept 42.1](#))—allowing them to become very abundant very quickly. If overcrowding occurs and food resources become limiting, populations can crash, leaving behind a few individuals that may ultimately serve to increase the population size through rapid clonal reproduction ([Figure 54.2](#)). Predatory insects such as the insidious flower bug can dampen these large swings in aphid population size, resulting in decreased resource limitation. Thus extrinsic factors such as predation can provide checks on populations, thereby limiting outbreaks, or on the other end, local extinctions.

Figure 54.2 Population Fluctuations of Aphids and Their Predators A population of soybean aphids (*Aphis glycines*) fluctuates more when its insect predator, the insidious flower bug (*Orius insidiosus*), is excluded than when it is present. Without the predator, soybean aphids cost soybean growers hundreds of millions of dollars in damage per year.

Population dynamics are controlled by the physical environment, biological interactions, and dispersal

Even though we know that populations fluctuate in space and time, determining the factors responsible for this variation can be challenging. Ecologists recognize three main factors that affect population dynamics and that act simultaneously to set limits for populations and species: the physical environment, biological interactions, and dispersal.

As you saw in [Chapter 53](#), the distribution and abundance of species are highly dependent on the physical environment; factors such as climate, topography, and even human infrastructure set physiological limits for species. Thus it makes sense that the physical features of the environment strongly limit a population's geographic extent and size through time. You saw this for *Clematis*, whose populations are restricted to dry, rocky limestone soils, resulting in a patchy distribution pattern.

Likewise, many types of biological interactions affect population dynamics. Interbreeding among individuals within populations affects their size and extent—in fact, many populations can be defined by the genetic similarity of the individuals within a given area (see [Key Concept 20.4](#)). For example, populations of wild endangered salmon, which look nearly identical to hatchery-raised salmon, can be assessed for population size using genetic techniques that allow differentiation among populations. In addition, because individuals within populations share similar resources, [intraspecific competition](#) (competition for shared resources by individuals of the same species) can be critical in controlling population size, as you will see in [Key Concept 54.2](#). * [Interspecific interactions](#) (interactions among individuals of different species) are another important factor in controlling population dynamics.

intraspecific competition Competition for shared limited resources by individuals of the same species.
--

Finally, dispersal can be a critical factor controlling population dynamics. Dispersal comes in many forms. It can be active when movement is controlled by the individual, such as you might see with elephants; passive when movement is controlled by the physical environment, as in corals and dandelions; or facilitated by active agents, such as birds or bats dispersing seed-laden fruits ([Figure 54.3](#)). Dispersal is a mechanism that can reduce competition for resources, either with a parent or another individual within the population. In addition, dispersal allows individuals to escape a harsh physical environment. Thus dispersal serves as a mechanism to reduce the probability of local extinctions of populations by spreading the risk among multiple populations that are geographically separated (see [Key Concept 54.4](#)).

(D)

Figure 54.3 Different Dispersal Mechanisms of Organisms (A) Elephants actively disperse, (B, C) corals and dandelions disperse passively, and (D) seeds within fruits are typically dispersed by an active agent, in this case, a toucan.

A specific type of dispersal is migration. **Migration** typically occurs in response to seasonal variation in resources, involves round-trip movement, and includes the whole population. For example, North Pacific populations of the humpback whale (*Megaptera novaeangliae*) migrate more than 3,000 miles between their winter breeding grounds in the south (Mexico, Hawaii, and Japan) and their summer feeding grounds in the north (Northeast Pacific coast and Gulf of Alaska) (**Figure 54.4**). Scientists determine whale migration patterns and population numbers by taking photographs and collecting genetic material to follow and compare individuals in the feeding and breeding grounds. A 2006 survey of North Pacific humpback whales determined that close to 20,000 individuals in five separate populations make the migration every year. Remarkably, there were only 1,400 North Pacific humpback whales in 1966, when commercial whaling of these populations was banned.

migration Roundtrip movement of individuals within a population as a consequence of seasonal variation in resources.

Figure 54.4 Migration of North Pacific Humpback Whales North Pacific populations of the humpback whale (*Megaptera novaeangliae*) migrate between their winter breeding grounds off Mexico, Hawaii, and Japan and their summer feeding grounds in the Gulf of Alaska and Northeast Pacific coast. A 2006 survey of North Pacific humpback whales determined that close to 20,000 individuals migrate in five separate populations (represented by different colored arrows).

As you can see, whale biologists use various techniques to estimate the population sizes of humpback whales. Let's consider in more detail the variety of approaches ecologists use to measure population size.

Ecologists use a variety of approaches to estimate population size and extent

Accurately measuring the size and extent of a population is harder than you might think. One challenge is determining the boundary of the population. If the area is self-contained and small enough, you might be able to simply count all the individuals of a particular species to get the population size. Biologists performed this type of count, called a **full census**, on the African elephant population of Samburu and Buffalo Springs National Reserves in Kenya. By monitoring the elephants for 21 months, the biologists learned to recognize each of the 760 individuals in the population, primarily by their unique and distinctive ear markings. But populations are often too large and too mobile for a full census; often the extent of the range of a population is not perfectly known. In these cases, ecologists instead determine the **population density**, or the number of individuals within a given area (or volume, for organisms living in water), and then extrapolate from these samples to estimate the total population size.

full census A count of every individual in a population.

population density The number of individuals in a population per unit of area or volume.

As you might imagine, estimating population densities is easiest for sessile organisms. Investigators need only count the individuals in a sample of representative locations and extrapolate the counts to the entire geographic range of the population. Individuals may be counted within a measured area called a **quadrat** or along a **transect**—a line drawn across an area within the range of the population (often designated by a tape measure marked at regular intervals). By making repeated counts with either of these methods, investigators can use these surveys to make reasonably good estimates of the size of a population.

quadrat A four sided measurement area of any size used to count the individuals within the area.

transect A linear measurement of any length used to count individuals along the stretch of the line.

Counting mobile organisms is more difficult because individuals move into and out of sampling areas, as you saw in the humpback whale example. In such cases, investigators may use the **mark-recapture method** ([Figure 54.5](#)). They begin by capturing, marking, and then releasing a number of individuals. Later, after the marked individuals have had time to mix with unmarked individuals in the population (but before enough time has elapsed for births, deaths, and individual movement to affect the population size significantly), another sample of individuals is captured. This sample is then used to obtain an estimate of the total size of the population in the sampling area. The extrapolation is achieved by applying the equation described in [Figure 54.5A](#), which assumes that the *proportion* of marked individuals in the second sample (i.e., individuals that were captured and marked in the first sample) is about the same as the proportion of individuals in the sampling area that were captured in the first sample.

mark-recapture method A method of estimating population sizes of mobile organisms by capturing, marking, and releasing a sample of individuals, then capturing another sample at a later time.

research tools

Figure 54.5A The Mark–Recapture Method The method described here is used to estimate animal population sizes for highly mobile species (such as *Ixodes scapularis*, the black-legged tick). Once a sampling area has been determined, investigators capture, mark, and then release the animals back into the population. The proportion of marked individuals recaptured in a second sample is assumed to be the same as the proportion of the total individuals in that sample to the population size within the area.

Figure 54.5B **work with the data** follows below.

work with the data

Figure 54.5B Monitoring Tick Populations

Original Paper: Falco, R. C. and O. Fish. 1988. Prevalence of *Ixodes dammini* near the homes of Lyme disease patients in Westchester County, New York. *American Journal of Epidemiology* 127: 826–830.

Lyme disease is a chronic and debilitating condition caused by spirochete bacteria of the genus *Borrelia*, which infect humans by way of the bite of an intermediate host, the black-legged tick (*Ixodes scapularis*), also known as the deer tick. (In 1993 *I. dammini* and *I. scapularis* were found to be one species.) The incidence of Lyme disease has increased dramatically in the past 20 years, particularly in the northeastern United States. In order to assess the risk of exposure to this disease in Westchester County, New York, investigators measured the abundance of deer ticks in suburban lawns near wooded areas using the mark–recapture method described in Figure 54.5A. (Ticks are typically collected by dragging a white cloth along the ground; the ticks latch onto the cloth in much the same way they would to a passing leg.) By drag-sampling one representative lawn, the researchers collected the data shown in the table.

	Original capture event	Second capture event (3 weeks later)
Adult ticks captured	180	33
No. of marked ticks	180 ^a	8

^aAll ticks captured in the first event were marked with acrylic paint and released.

QUESTIONS

- Refer to Figure 54.5A. Using the equation and other information described in that figure, estimate the total number of adult ticks in the sampled lawn from the data table above.
- The lawn was approximately 700 m² in size. What is the approximate density of ticks per square meter?
- What do you think might be the implications of this study for residents of this neighborhood?

A similar **work with the data** exercise may be assigned in **LaunchPad**.

More recently, ecologists have used DNA analysis to determine how many unique individuals might be contained within a population. In some cases, instead of capturing individuals and collecting DNA, ecologists collect the next best thing—tissues, fur, or feces left behind by organisms in their natural habitat to be analyzed for DNA signatures. In a novel twist on sample collection, some ecologists have even trained dogs to locate feces of some hard to find species such as orca whales. With enough samples, the extent and size of populations can then be determined for species that are hard to survey in the wild.

54.1 recap

Species are divided into groups of individuals, or populations, that can vary spatially across their geographic range. All populations change in size and spatial extent due to the physical environment, biological interactions, and dispersal. Ecologists use a variety of approaches to estimate population sizes, including full censuses, surveys using quadrats or transects, mark-recapture methods, and DNA analyses.

learning outcomes

You should be able to:

- Use examples to illustrate how species are divided into populations, metapopulations, and geographic ranges.
- Describe and compare the three main factors that control population dynamics over time.
- List and describe major approaches that ecologists use to estimate population size and extent.
- Given a description of a population, choose and justify the most appropriate method for estimating its population size and/or extent.

1. Refer to [Figure 54.4](#). Draw a diagram showing which populations of humpback whales interact on their summer feeding grounds. Do you think all five populations make up one metapopulation during the summer? Explain.
2. Refer to [Figure 54.2](#). What type of species interaction appears to have caused the aphid population to fluctuate in size? What type of species interaction keeps the population size from fluctuating?
3. What are some of the ways in which population size and geographic extent of organisms can be measured?
4. A researcher wants to determine how many leopard frog tadpoles are present in a pond in the spring. Later, after the tadpoles have metamorphosed, she wants to compare this number with the size of the frog population. What method should the researcher use to determine the population sizes? Explain your answer.

Quantifying population sizes in space and time provides valuable information on the dynamics of a species, but those observations alone cannot explain how, when, and why populations change in size. In order to understand and predict population sizes through time, ecologists characterize population growth, or the change in population size over time, using quantitative methods.

***connect the concepts** Interspecific interactions such as competition, predation, and positive interactions (i.e., mutualisms and commensalisms) often set the upper limits on the number of individuals within populations. See [Chapter 55](#).

54.2 Population Growth Describes the Change in Population Size over Time

It is clear from the previous section that populations are constantly changing in size. [Population growth](#) describes the change in population size over time. For example, you read that North Pacific humpback whales experienced dramatic declines in population size from commercial whaling, but when hunting was banned, the populations rebounded from 1,400 whales in 1966 to nearly 20,000 in 2006. Measuring how a population changes over time requires following its [demography](#): births, deaths, immigration, and emigration.

population growth rate The rate of change in population size over time.

demography The study of how births, deaths, immigration, and emigration affect population changes over time.

focus your learning

Population size and growth rate are measured by the numbers of births, deaths, and migrants into and out of the population over time.

Population growth can be limited by density-dependent and density-independent factors.

Life tables help predict how age-related survival and reproduction affect population growth.

Births increase and deaths decrease population size over time

Over any given interval of time, the size of a population increases by the number of individuals added to the population by births and by immigration (the movement of individuals into the population from elsewhere) and decreases by the number of individuals lost from the population by deaths and by emigration (individuals leaving the population to go elsewhere). This relationship is expressed mathematically as

$$N_t = N_0 + (B - D) + (I - E) \quad (54.1)$$

where N_t = the population size at time t , N_0 = the population size at time 0, B = the number of individuals born between time 0 and time t , D = the number that died between time 0 and time t , I = the number that immigrated between time 0 and time t , and E = the number that emigrated between time 0 and time t .

As you saw earlier, population size rarely remains the same but instead changes over time. We can use [Equation 54.1](#) to estimate how population size changes over the interval of time 0 to t and get a population growth rate, or the rate of change in population size over time. This can be expressed mathematically as

$$\Delta N = (B - D) + (I - E), \text{ or the change in } N \text{ (} \Delta N \text{) for the time interval 0 to } t$$

To understand population growth rate from births and deaths alone, ecologists often assume a

“closed system” that does not include immigration and emigration. This simplifies the equation to

$$\Delta N = (B - D) \Delta t \quad (54.2)$$

The change in population size can then be calculated if one knows the number of births (B) and deaths (D) that have occurred over a given period of time. The birth and death numbers will naturally depend on the size of the population and the time interval considered. As a result we need to convert B and D into rates that will allow us to estimate population growth for any change in population size over time. Therefore we can further express B and D as

$$B = bN_0$$

where B is the product of the per capita birth rate (b) (i.e., the number of births per individual per unit of time) and N_0 (population size at time 0). Likewise, the death rate can be calculated as

$$D = dN_0$$

where D is the product of the [per capita death rate \(\$d\$ \)](#) (i.e., the number of deaths per individual per unit of time) and N_0 (population size at time 0).

per capita death rate (d) In population growth models, the average individual's chance of dying in some time interval.

The term “per capita” literally translates to “per head” and is meant to indicate births and deaths per individual in the population. The change in the total number of births and deaths can then be calculated by multiplying the per capita birth and death rates by the population size at N_0 . Here's what that looks like mathematically:

$$\Delta N = bN_0 - dN_0 \text{ or } \Delta N = (b - d)N_0 \Delta t = bN_0 \Delta t - dN_0 \Delta t \text{ or } \Delta N = (b - d)N_0 \Delta t$$

The difference between the [per capita birth and death rate](#) ($b - d$) is the per capita growth rate and is symbolized by r . Substituting r for $(b - d)$, we get

per capita birth rate (b) In population growth models, the average number of offspring that an individual produces over some time interval.

$$\Delta N = rN_0 \Delta t \quad (54.3)$$

This simple model reflects why populations change in size. A population will increase in size if the per capita birth rate exceeds its per capita death rate; that is, if $b > d$, then $r > 0$. Likewise, the population will decline in size if $b < d$, or $r < 0$. If $b = d$, then $r = 0$, and the population will not change in size.

Ecologists use differential calculus to express the change in population size (ΔN) over very short, instantaneous periods of time (dN/dt). In this way, they are assuming that population growth is continuous, meaning the time interval is infinitely small and the growth curve will be smooth. This is expressed by

$$\frac{dN}{dt} = rN_0 \quad (54.4)$$

Once we have a value for r , and we know population size, we can use it to characterize patterns of growth in populations through time. One pattern of growth that occurs when populations are not limited by resources is exponential growth, which we discuss next.

All populations have the potential for exponential growth

You know from [Equation 54.4](#) that a population will grow, over some time period, as long as the per capita growth rate, r , is greater than zero (that is, when $b > d$). During this time period, the population will add a number of individuals that is r times its initial size. As the number of individuals in a population (N_0) increases, the number of new individuals added per unit of time accelerates—that is, rN_0 increases—even though the per capita growth rate (r) remains constant ([Figure 54.6](#)). This multiplicative pattern is known as **exponential growth**. It is also clear from [Figure 54.6](#) that the value of r can make a big difference in the rate of growth of the population—a population with $r = 1.00$ will have a much faster rate of growth than a population with $r = 0.25$, even though both populations will display an exponential growth pattern.

Figure 54.6 Exponential Population Growth Rate Exponential population growth occurs when the size of a population changes by a constant proportion over time. This graph compares the exponential growth of two populations that vary in their values of r .

Q: Which curve, blue or red, has the faster population growth rate?

Activity 54.1 **Exponential Population Growth Simulation**

www.Life11e.com/ac54.1

exponential growth A pattern of population growth characterized by a multiplicative pattern in which, as the number of individuals increases, the number of new individuals added per unit time accelerates. (Contrast with logistic growth.)

[Equation 54.4](#) gives us the exponential growth of a population, but it does not allow us to predict the size of a population at a later time. Using calculus, we can integrate [Equation 54.4](#) and get

$$N_t = N_0 e^{rt} \quad (54.5)$$

where N_t = the population size at time t , N_0 = the population size at time 0, e = a constant, the base of the natural log ($e = 2.718$), r = per capita growth rate, and t = the time interval between time 0 and time t . Knowing the starting population size and the per capita growth rate, we can use [Equation 54.5](#) to forecast the population size at some later time, assuming exponential growth. This is similar to the equation banks use to calculate compound interest on a loan.

One application of projecting population sizes into the future comes in the form of predicting human population growth. The human population increased relatively slowly until 1825, when it was 1 billion, and now stands at 7.4 billion ([Figure 54.7](#)). United Nations data show that world population growth rates have fallen from a high of 2.30 percent (note that the percent population growth rate is $r \times 100$) in the early 1960s to 1.18 percent today (**Investigating Life: Will the Global Human Population Growth Rate Decline?**). Projections indicate that human population growth rates will continue to decline to 0.50 percent in 2050 and to 0.10 percent in 2100, leading to a “best estimate” population size of 9.1 billion by 2050 and 11 billion by 2100. These projections in human population size beg the question: will world resources be able to sustain such large populations into the future? Is 11 billion above the maximum number of humans that can be supported sustainably on Earth? We will consider these questions at the end of the chapter.

Figure 54.7 Explosive Growth of the Human Population Human population growth was relatively slow until 1825, but advances in technology since then have allowed it to grow at an exponential rate.

investigatinglife Will the Global Human Population Growth Rate Decline?

experiment

Original Paper: United Nations, Department of Economic and Social Affairs, Population Division. 2015. World Population Prospects: The 2015 Revision, Methodology of the United Nations Population Estimates and Projections, Working Paper No. ESA/P/WP.242.

Understanding the demographic changes in human populations over the coming years is critical in anticipating and planning for such challenges as food production, energy and water consumption, emerging diseases, and climate change facing our planet. The 2015 revision of World Population Prospects is the U.N.'s 24th round of official population estimates and projections. It builds on the previous reports by incorporating results from the most up-to-date national population censuses as well as findings from recent demographic and health surveys that have been carried out around the world.

HYPOTHESIS▶ World population growth rates have declined since 1950 and will continue to decline in the next century.

METHOD

1. Census and demographic survey data on survivorship, fertility, and international migration were gathered for 201 countries over the period 1950 to 2015.
2. The demographic data were used to establish parameters for life tables (similar to Table 54.1) in order to determine human population growth rates from 1950 to 2015.
3. To project the change in population growth rate values up to 2100, demographic data were used to make assumptions on future trends

in human survivorship, fertility, and international migration. Because the future is uncertain, several different projections were produced to understand their possibility of variability and arrive at a "best estimate" of the change in population growth.

RESULTS

Population growth rates fluctuated after 1950 but dropped from a high of 2.30% in the early 1960s to 1.18% in 2015. Projections indicate that human population growth rates will continue to decline to 0.50% in 2050 and to 0.10% in 2100. Note that the percentage population growth rate is equivalent to $r \times 100$.

CONCLUSION▶ Population growth rates have dropped substantially in the last 65 years and are projected to continue this trend into 2100.

work with the data

Here you will use the population growth rate from above to project the human population size on Earth in the future.

QUESTIONS

1. Using Equation 54.5, the population size in 2015 (7.4 billion), and the population growth rate for 2015 (1.18%, above), estimate what the world's population size would be in 2100.
2. Projections indicate that if the human population growth rate declines to 0.50% in 2050, the population size will be 9.1 billion by 2050 and 10 billion by 2080. Using the projected population size and growth rate in 2080, project the human population size in 2100.
3. Suppose the carrying capacity of Earth is 12 billion people. Using Equation 54.7, project the human population size in 2100, given the 2015 data and 2080 data.
4. Given your calculations in Question 3, will Earth's carrying capacity for humans be reached under either scenario by 2100? Which parameter (population growth rate or carrying capacity) is projected to most reduce population size by 2100?

A similar **work with the data** exercise may be assigned in **LaunchPad**.

Some populations may grow at rates close to their maximum, depending on the circumstances. During the 39 years following the ban on commercial whaling, North Pacific humpback whale populations grew exponentially at a rate of 5-7 percent per year. Since the whales were released from hunting, they have had ample habitat, abundant food, and no predators, so there appears to be little limiting their population growth at this point. However, changes in ocean conditions and thus food resources, entanglement in fishing gear, ship strikes, whale-watching harassment, and harvesting for scientific purposes all pose potential threats to humpback whale population recovery. In addition, there is some limit to the population sizes whales can attain, given intraspecific competition for food resources and breeding areas.

We will turn next to what happens to population growth when limiting resources affect the number of births and deaths within a population.

Logistic growth occurs as a population approaches its carrying capacity

What would happen if all the offspring produced by a population survived and reproduced? The prospects are alarming. In 1911 L. O. Howard, then chief entomologist of the U.S. Department of Agriculture, estimated that if all the offspring of the common house fly (*Musca domestica*) were to survive, a pair of flies beginning to reproduce on April 15 would produce a population of 5,598,720,000,000 adults by September 10 of the same year. Given such amazing reproductive capacities, it is clear that forces exist to limit the growth of fly populations (and populations of every other organism).

No real population can maintain exponential growth for long periods of time. As a population increases in density, the resources it requires—such as food, nest sites, and shelter—become depleted, causing birth rates to drop and death rates to rise. In other words, birth rates and death rates are dependent on the density of the population. Populations may initially grow rapidly when the population is small, but as populations increase in size, density-dependent birth and death rates cause r to decline toward zero, a pattern of population growth called **logistic growth**. Eventually when $r = 0$, the population stops changing in size because births equal deaths. Thus instead of continuing to increase exponentially, population growth slows down and the population eventually levels off at some size known as the **carrying capacity** or K (Focus: **Key Figure 54.8**). K can be thought of as the number of individuals that any particular environment can sustain indefinitely. If the number of individuals in the population exceeds K , then r will be negative until population size reaches K once again. Likewise, if the number of individuals falls below K , then r will be positive until population size reaches K .

logistic growth A pattern of population growth characterized by a multiplicative pattern that eventually levels off as density dependent processes slow growth at some carrying capacity (Contrast with exponential growth.)

carrying capacity (K) The maximum number of individuals in a population (i.e., maximum population size) that can be supported by the resources present in a given environment.

focus: key figure

Figure 54.8 Population Growth Models: Exponential versus Logistic Growth

Exponential population growth (red J-shaped curve) is much faster than logistic population growth (blue S-shaped curve), which is limited by the density or carrying capacity of the population.

Q: How does exponential growth differ from logistic growth?

 **Activity 54.3 Logistic Population Growth Simulation** www.Life11e.com/ac54.3

To model logistic growth, the exponential growth equation is modified by adding a term, $(K - N_0)/K$, which represents the fraction of the carrying capacity (K) that is available for population growth. As long as the population size is less than the carrying capacity (i.e., $N_0 < K$), only a fraction of the available resources are being used. As the population size approaches the carrying capacity, however, the fraction of resources available for any new individual becomes smaller. The logistic growth equation is simply the exponential growth rate rN_0 multiplied by $(K - N_0)/K$ to get

$$\frac{dN}{dt} = rN_0 \left(\frac{K - N_0}{K} \right) \quad (54.6)$$

Population growth should stop when $N_0 = K$ because at that point, $K - N_0 = 0$, so $(K - N_0)/K = 0$, and thus $dN/dt = 0$ and the population will remain at a constant size.

Just as you saw with [Equation 54.5](#), we can integrate [Equation 54.6](#) to allow us to predict the population size at some later time, assuming logistic growth. When we do this we get

$$N_t = K \left[1 + \left(\frac{K - N_0}{N_0} \right) e^{-rt} \right]^{-1} \quad (54.7)$$

where N_t = the population size at time t , N_0 = the population size at time 0, e = a constant, the base of the natural log ($e = 2.718$), r = per capita growth rate, K = carrying capacity, and t = the time interval between time 0 and time t . In this case, knowing the starting population size, the per capita growth rate, and the carrying capacity of the population, we can use [Equation 54.7](#) to

forecast population size at some later time, assuming logistic growth.

Activity 54.2 Population Growth www.Life11e.com/ac54.2

Factors limiting population growth can be density- dependent or density-independent

As you just saw, the density of a population can have large effects on population growth and ultimately the size of a population through time. **Density-dependent** factors can include:

density-dependent Factors such as limiting resources, predators, or pathogens that have a negative effect on population size as a consequence of the density of individuals. (Contrast with density-independent.)

Limiting resources. As a population increases, it depletes its resources as a result of intraspecific competition.

Predators may be attracted to areas with high densities of their prey, allowing them to capture a larger proportion of individuals and causing the death rate of the prey population to rise.

Pathogens may spread more easily in dense populations than in populations with fewer individuals, resulting in a rise in the death rate.

It is important to note that density does not always cause a decline in population growth. Some populations grow better, albeit up to some limit, when population densities are higher rather than lower; this is known as the **Allee effect** (named after the ecologist W. C. Allee, who first described it). Sometimes individuals survive better in a group than on their own, as you saw with the predator avoidance strategies used by wood-pigeons and ground squirrels living within groups (see [Figure 52.21](#)).

Allee effect An increase in the population growth rate (r) as the population density decreases.

Moreover, not all factors that change population size act in a density-dependent manner. A period of extreme cold, or an exceptionally strong hurricane, may kill a large number of individuals in a population regardless of the population's density; such an event is **density-independent** and may be a significant factor in depressing growth and keeping populations from reaching their carrying capacity.

density-independent Factors such as the physical environment that have a negative effect on population size independent of the density of the population. (Contrast with density-dependent.)

Life tables keep track of demographic events

Up to this point we have assumed that individuals within a population do not vary in their birth and death rates. This is a big assumption given that we know real populations are made up of individuals of different ages, sizes, and sexes, which vary in their capacity to reproduce or survive. For example, a newborn whale or human cannot reproduce immediately, but must mature to reproductive age. Likewise, the likelihood of death will vary depending on the age of

the individual. Ecologists use a form of accounting, known as a **life table**, to keep track of how demography will affect the growth rate of the population. Life tables summarize how survival and reproductive rates vary with the age, size, or sex of the individuals within a population. These summaries can then be used to predict future population trends and develop strategies for managing populations of commercial or ecological value. They are also used by life insurance companies to determine how much to charge people of different ages for insurance policies.

life table A summary of how survival and reproductive rates vary with the age, size, or sex of individuals within a population, and used to estimate population growth rate.

Let's consider an example of a life table from the literature. **Table 54.1** shows a cohort life table using data from the acorn barnacle *Balanus glandula* on the shorelines of Scotland. A **cohort life table** uses a cohort—a group of individuals born within the same time frame—from the larger population to estimate growth rate. The two columns on the left show the number of individuals surviving and the number of offspring produced at different ages (x) through time. As the number of individuals within the cohort die, N_x decreases from 1 million barnacles to only 2 barnacles after 8 years. The proportion of individuals that survive, known as survivorship (l_x), can be calculated by simply dividing N_x by N_0 , or the number of barnacles originally born into the cohort (represented by age 0). In addition, we can calculate the **fecundity (m_x)**, or the mean number of barnacle offspring produced per surviving adult barnacle per age class, by dividing the total number of offspring (N_x offspring) by the number of individuals (N_x) that produce those offspring. Multiplying survivorship (l_x) by fecundity (m_x) gives us the number of offspring produced for individuals within a particular age class within the population. The sum of these values for all the age classes gives us the **net reproductive rate, R_0** , which is simply the mean number of offspring produced per individual in the cohort, adjusted for survival:

table 54.1 Cohort Life Table for the Barnacle *Balanus glandula*^a

Age (x)	Number of individuals (N_x)	Number of offspring (N_x offspring)	Survivorship (l_x)	Fecundity (m_x)	$l_x m_x$	$x l_x m_x$
0	1,000,000	0	1	0	0	0
1	62	285,200	0.000062	4,600	0.285	0.285
2	34	295,800	0.000034	8,700	0.296	0.592
3	20	232,000	0.000020	11,600	0.232	0.696
4	15	190,500	0.000015	12,700	0.191	0.764
5	11	139,700	0.000011	12,700	0.140	0.700
6	6	76,200	0.000006	12,700	0.076	0.456
7	2	25,400	0.000002	12,700	0.025	0.175

1 To estimate the per capita growth rate, r , sum all l_x by m_x values to get the **net reproductive rate, R_0** .
 $R_0 = \sum (l_x m_x) = 1.27$

2 Then, sum all l_x by m_x by x values and divide by R_0 to get the generation time, G .
 $G = \sum (x l_x m_x) / R_0 = 3.05$

3 Finally, divide the natural log of R_0 by G to get the intrinsic rate of increase, r .
 $r = (\ln R_0) / G = 0.08$

^aThe life history of barnacles involves releasing larvae into the water column, where they feed and undergo a series of larval stages. Eventually they settle back on the rock and metamorphose into juvenile barnacles, which grow into reproductive adults.

cohort life table A life table in which the fate of a group of individuals born during the same time frame (a cohort) is followed from birth to death.

fecundity (m_x) The average number of offspring produced by each individual (or female) within the population.

net reproductive rate (R_0) The mean number of offspring produced by an individual in a population during its lifetime.

$$R_0 = \sum(I_x m_x) \quad (54.8)$$

If R_0 is greater than 1.0, there is a net increase in offspring produced each generation, and assuming the birth and death rates do not change over time, the population should increase exponentially. If R_0 is less than 1.0, and individuals are not replaced as they die, the population declines eventually to extinction. If R_0 is 1.0, then the births and deaths balance out and the population will not change in size.

We can use R_0 to estimate the per capita growth rate, r , of a cohort by scaling R_0 to account for the generation time of the cohort. The generation time, G , is the average age of the parents of all the offspring produced within the cohort (see [Table 54.1](#) for equation). To estimate r , we simply divide the natural log ($\ln$) of R_0 by G and get

$$r = (\ln R_0) / G \quad (54.9)$$

Cohort life tables follow individuals from birth to death as a function of calendar year or life stage (e.g., eggs, larvae, pupae, and adults in insects). This is relatively easy to do if the organisms are easily followed—for example, if they are sessile and short-lived as we saw in the barnacle example. For organisms that are harder to track, a static life table can be constructed by sampling a population at a single slice of time. Here the numbers of individuals and their reproduction for different age classes are recorded at one time and used in a similar way to those data in [Table 54.1](#) to calculate the net reproductive rate and per capita growth rate of the population.

The construction of life tables has allowed ecologists to observe common life history patterns, reflecting common solutions to ecological challenges, across a tremendous diversity of organisms. For example, the number of individuals surviving through each life stage (survivorship, l_x) can be taken from a life table and plotted graphically to construct a survivorship curve. Typically, a [survivorship curve](#) is constructed for a hypothetical cohort, usually of 1,000 individuals, by plotting the numbers of individuals expected to survive to reach each age category on a logarithmic scale.

survivorship curve A plot of the number of individuals surviving through each life stage (survivorship, l_x) for a hypothetical cohort, usually of 1,000 individuals; includes three general curves called type I, II, and III.

Survivorship curves tend to take one of three general shapes:

Species with [type I survivorship curves](#) experience high overall survivorship through adulthood but steep declines late in life (the curve is concave) ([Figure 54.9A](#)). Species with this type of survivorship curve (humans, elephants, whales, and many other large mammals) typically have low reproduction rates but provide parental care to their offspring, which reduces the risk of death in early stages of development.

Species with [type II survivorship curves](#) face a constant risk of mortality at all ages (the curve is linear) ([Figure 54.9B](#)). Many birds, fish, and plants display this pattern.

Species with [type III survivorship curves](#) experience low survivorship early in life and higher survivorship once they reach maturity (the curve is convex) ([Figure 54.9C](#)). Species with this type of survivorship curve (most insects; marine invertebrates, including the barnacle in [Table 54.1](#); and annual plants) tend to produce many offspring but provide little or no parental care.

type I survivorship curve A survivorship curve in which individuals experience high overall survivorship through adulthood but a steep decline late in life. (Compare with type II survivorship curve, type III survivorship curve.)

type II survivorship curves A survivorship curve in which individuals experience a constant chance of surviving at all ages. (Compare with type I survivorship curve, type III survivorship curve.)

type III survivorship curve A survivorship curve in which individuals experience low survivorship early in life and higher survivorship once they reach maturity. (Compare with type I survivorship curve, type II survivorship curve.)

Figure 54.9 Survivorship Curves Ecologists recognize three general types of survivorship curves. Notice that the number of survivors has been plotted on a logarithmic scale. Three species provide real-world examples of the three types of life histories.

Q: What type of survivorship curve do humans have?

Activity 54.4 **Age Structure and Survivorship Simulation**

www.Life11e.com/ac54.4

Species survivorship curves help us classify how mortality plays out in populations over time, but many species have patterns of survivorship somewhere in between these extremes. For example, some organisms show a “stair-stepped” curve, with bouts of mortality during vulnerable periods of their life, followed by periods of relatively low mortality.

54.2 recap

Population growth is the change in population size over time, as reflected by the number of births, deaths, and migrants in and out of the population. Exponential (multiplicative) growth occurs when the per capita growth rate, r , is constant over time. Logistic growth occurs in an environment in which resources are limited and a population reaches its carrying capacity, K . Factors limiting population growth can be density-dependent (e.g., competition for food or space) or density-independent (e.g., physical environmental conditions). Life tables summarize how survival and fecundity vary with the age, size, or sex of the individuals in a population, and predict how these demographic events affect population growth.

learning outcomes

You should be able to:

- Write an equation for population size at time t , and explain each of the terms of the equation.
 - Distinguish between density-dependent and density-independent factors in population growth, and give examples of each.
 - Interpret a life table, and explain and calculate the types of information it can provide about a population.
-
1. Write an equation that describes how births, deaths, immigration, and emigration affect population size. Define each variable.
 2. Suppose you are asked to predict what the population size of an endangered bird will be in 2035.
 - a. Complete the cohort life table below, and calculate the R_0 , G , and r of this cohort.
 - b. Calculate what the population size, N_t , of this cohort will be in 2035, assuming exponential population growth and $N_0 = 120$.
 - c. To add more realism to these calculations, suppose that K (carrying capacity) = 300 for this cohort. What will the population size be, assuming logistic growth, in 2035?
 3. Plot the number of birds surviving with age for the cohort in Question 2. What type of survivorship curve does this cohort have?
 4. Describe some density-dependent and density-independent factors that could control the population growth of the bird cohort in Question 2.

Year	Age (x)	Number of female birds (N_x)	Number of female offspring (N_x offspring)	Survivorship (l_x)	Fecundity (m_x)	$l_x m_x$	x $l_x m_x$
2012	0	100	0				
2013	1	50	75				

2014	2	40	80
2015	3	30	60

Life tables reflect the ways in which organisms partition their time and energy among growth, maintenance, and reproduction. Comparisons across individuals, populations, and species reveal different patterns of partitioning, which allow organisms to cope with different environmental challenges. Let's move on to discuss how life history traits arise and the types of strategies organisms employ.

54.3 Life History Is the Lifetime Pattern of Growth, Reproduction, and Survival

We know as humans that individuals vary widely in when they mature, when and how many children they have, and when they die. This lifetime pattern of growth, reproduction, and survival is known as an individual's **life history**. In addition to the variation we see in life history patterns at the individual level, all species have a common **life history strategy** that helps define the average timing and nature of important life history events (**Figure 54.10**). Life history strategies are shaped by the way individuals within and among species allocate resources to growth, reproduction, and survival based on genetic and environmental factors. For example, in the case of humans today, the average age of puberty is 11 years, the average woman has one child at a time (except in the rare cases of multiple births), and the average life span is 70 years. These life history statistics are a product of the environmental and genetic constraints placed on humans in the twenty-first century. But they also belie the fact that human life history traits have changed dramatically from historical times and vary widely among populations around the world. Thus, as you will see, life history patterns not only vary within and among species but also through time.

life history The lifetime pattern of growth, reproduction, and survival for an average individual.

life history strategy The way in which individuals within and among species allocate resources to growth, reproduction, and survival based on genetic and environmental factors.

Figure 54.10 A Life History Strategy The timing and nature of life history events shape the overall life cycle of an organism. The life history strategy of this frog species reflects how environmental and genetic factors affect strategies to optimize growth, reproduction, and survival.

focus your learning

Life history strategies arise within and among species as a result of environmental and genetic constraints, resulting in trade-offs.

Life history strategies vary across a continuum from maximum population growth (*r*-strategists) to minimum population growth (*K*-strategists).

Life history strategies can vary at species and population levels

Life history strategies can vary among species, even for species that are taxonomically closely related, as a consequence of environmental differences. For example, on Mount Kenya two species of unusual plants in the genus *Lobelia* live in different types of habitats ([Figure 54.11](#)). One species, *Lobelia telekii*, lives on the dry rocky slopes of the mountain, where it reproduces only once (a strategy called [semelparity](#)), produces vast numbers of small seeds, and has a short life span. In the moist valley bottoms, another species, *Lobelia keniensis*, reproduces more than once (a strategy called [iteroparity](#)), produces fewer but larger seeds per reproductive event, and lives longer. Semelparity is typical of organisms whose probability of dying remains high even when they reach adulthood; it is seen in some fish, many insects, and all annual plants. In contrast, iteroparity is typical of organisms with long life spans. For example, because environmental conditions within the nests of social insects such as honey bees and ants are remarkably stable, iteroparity is the rule among these species; some queens live 10 years or longer and reproduce over their entire adult lives.

(A) *Lobelia telekii*

(B) *Lobelia keniensis*

Figure 54.11 Related Species with Vastly Different Life History Strategies On Mount Kenya, Africa, **(A)** *Lobelia telekii* lives on the dry rocky slopes of the mountain, where it reproduces once (is semelparous), produces many seeds, and has a short life span. In the moist valley bottoms, **(B)** *Lobelia keniensis* reproduces multiple times (is iteroparous), produces fewer but larger seeds, and lives longer.

semelparity Reproducing only once in a lifetime. (Contrast with iteroparity.)

iteroparity Reproducing multiple times in a lifetime. (Contrast with semelparity.)

Life history strategies can also vary within species at the population level. For example, some populations of guppies (*Poecilia reticulata*) in Trinidad live in streams where they are attacked and eaten by larger fish ([Figure 54.12](#)). But some streams have waterfalls that predatory fish are unable to negotiate. Guppies that live in the predator-free areas upstream from those waterfalls have lower death rates compared with guppies below the falls. To see whether the risk of being eaten by a predator influenced the life history strategies of these guppies, David Reznick and his colleagues collected guppies from high-predation and low-predation sites and raised them in the laboratory. Some guppies from each group were provided with plentiful food, and others with limited food, to simulate the variation the fish would typically encounter in their home streams. In the laboratory, where no predators were present, guppies from high-predation sites matured earlier, reproduced more frequently, and produced more offspring in each brood than did guppies from low-predation sites, no matter how much food the guppies received. The investigators concluded that predation had genetically selected for early and frequent reproduction in the guppies living below the falls.

Figure 54.12 Predation Affects the Life History of Guppies In Trinidad, populations of guppies (*Poecilia reticulata*) from high-predation stream sites below the falls matured earlier, reproduced more frequently, and produced more offspring per brood compared with guppies from low-predation stream sites above the falls, no matter how many resources the guppies were given.

Q: Are the life history strategies of the two guppy populations, either from high-predation

streams and low-predation streams, likely genetically determined? Why?

Perhaps the best-studied example of how life history traits can vary not only among populations, but also among individuals, is the case of human life span. Human life span varies widely around the world and between the sexes ([Figure 54.13](#)). Today, humans live on average to 87 years in Japan, Hong Kong, and many European countries, and to 35-50 years in some African countries (e.g., Sierra Leone, Democratic Republic of the Congo, and Somalia) where HIV infection, famine, and war are common. In the United States, average life span is 80 years, with women outliving men by 5 years. Research has shown that the factors contributing to lower life expectancy rates in men include higher rates of homicide, accidental death, and parasitic and infectious diseases.

Figure 54.13 Human Life Expectancy around the World Comparison of male and female life expectancy at birth for a variety of countries in 2016. The solid black line corresponds to equal female and male life expectancy. The sizes of the bubbles are linearly proportional to the population of the country.

For the most part, the large variability in life span we see in humans can be attributed to environmental factors. If you lived during the Bronze Age, your life expectancy was 28 years, and it was not much better even in the early nineteenth century (about 35 years). Reduction in infant mortality has accounted for most of the increase in life expectancy, but since the end of the 1950s the mortality rate of those older than 80 years has decreased by 1.5 percent each year. Much of the increase in life expectancy that we enjoy today is the result of modern advances in human health and nutrition, which begs the question: Is there a limit to human life expectancy? One study, which plotted human life-span data over time, shows a remarkable linear relationship with no leveling off yet, that might indicate an upper limit ([Figure 54.14](#)). In fact, because life span has increased by 2.5 years every decade for the last 150 years, one possible scenario is that 60 years from now the average person's life span will reach 100 years!

While some limit on human lifespan is mostly certain, these predictions suggest that human life expectancy is a highly flexible life history trait indeed.

Figure 54.14 Human Life Expectancy—Past, Present, and Future Recorded human female life expectancy from 1840 to the present. The linear trend in life expectancy is depicted by the bold line, and the extrapolated trend by the dashed gray line. Based on the trend, in 2040 the average woman might have a life span of 95 years.

Q: Compare the differences in female life expectancy between 1840-1940 and 1940-2040. Is the rate of change in life expectancy predicted to increase?

Life history strategies arise from constraints on growth, reproduction, and survival

As it should be clear by now, the fitness of a population or species is highly dependent on its life history strategy in relationship to its surrounding environment. Thus it makes sense that genes that maximize growth, reproduction, and survival would be favored by natural selection, resulting in an optimal life history strategy for that species or population. However, there are ***constraints on optimality**, resulting in **trade-offs** in life history traits that put limits on the possible life history outcomes for species.

trade-off The relationship between the fitness benefits conferred by an adaptation and the fitness costs it imposes. For an adaptation to be favored by natural selection, the benefits must exceed the costs.

Trade-offs include allocation of resources to such traits as growth versus reproduction or number of offspring versus their size. Energy devoted to one life history trait can reduce the amount available for others. For example, the growth of Douglas fir trees (*Pseudotsuga menziesii*) measured using annual growth ring size is negatively correlated with cone

production. The more cones the tree produces, the narrower the width of the rings, suggesting that the allocation to reproduction takes energy from growth. Another trade-off that can have dramatic consequences for population growth is that of survival and reproduction. An example of this occurs in the giant Pacific octopus (*Enteroctopus dofleini*), which lives only 3-5 years and dies soon after significant parental investment in its thousands of offspring.

As you have seen, much of the variation in life history traits appears to result from an evolutionary response to environmental variability. Generally, unpredictable environments are associated with greater allocation to reproducing quickly, shorter life spans, and correspondingly high per capita growth rates. Conversely, predict-able environments, where organisms must compete for high-quality resources, are associated with lower fecundity, longer life spans, and correspondingly lower per capita growth rates. Species whose life history strategies allow for high population growth rates are called [r-strategists](#), and species whose life history strategies allow them to persist at or near the carrying capacity (K) of their environment are called [K-strategists](#) ([Figure 54.15](#)). Keep in mind, however, that these categories are extremes; most species fall along a continuum between these two strategies.

r-strategist
A species whose life history strategy allows for a high intrinsic rate of population increase (*r*). (Contrast with *K*-strategist.)

K-strategist
A species whose life history strategy allows it to persist at or near the carrying capacity (*K*) of its environment. (Contrast with *r*-strategist.)

Level	<i>r</i> -strategists	<i>K</i> -strategists
Habitat	Tolerate unpredictable conditions by using a wide variety of resources	Thrive in predictable environments but compete for high-quality resources
Reproductive strategy	Typically reproduce once (semelparity), but greater allocation to reproduction than growth results in large numbers of offspring	Reproduce more than once (iteroparity), but greater allocation to growth than reproduction results in fewer offspring
Survivorship	Short life span, density-independent mortality, typical of a type III survivorship curve (see Figure 54.9C)	Long life span, density-dependent mortality, typical of a type I or II survivorship curve (see Figure 54.9A , B)
Population growth	Period of exponential growth (<i>r</i>) followed by periodic or seasonal population declines	Slowly rising population growth that stabilizes at or near carrying capacity (<i>K</i>)
Examples		

Figure 54.15 Two Life History Strategy Extremes Species whose life histories are geared to achieve the maximum possible rate of population growth are referred to as *r*-strategists; those whose population dynamics are bounded by carrying capacity are

K-strategists. The life histories of most species fall along a continuum between these two strategies.

For *r*-strategists, life is uncertain. Individuals tend to reproduce only once and to produce large numbers of offspring, most of which are expected to die early in life (that is, they have a type III survivorship curve; see [Figure 54.9C](#)). They can generally use a wide variety of resources and tolerate a wide range of conditions. *K*-strategists are adapted to predictable conditions, are long-lived, and reproduce several times; their smaller numbers of offspring have a high probability of surviving to adulthood (that is, they have a type I or II survivorship curve; see [Figure 54.9A, B](#)). *K*-strategists tend to be good at enduring competition for resources, but this sometimes leads to trade-offs in reproduction.

That life history trade-offs can evolve is suggested by genetic correlations among suites of life history traits. Such genetic correlations imply either simultaneous selection on two or more life history traits or *** linkages** among the genes that code for those traits. Across *Drosophila melanogaster* strains, for example, a high per capita rate of growth is correlated with the ability to reproduce under starvation conditions and with the ability to develop on a variety of media in the laboratory—both of which are consistent with the *r* strategy of tolerating a wide range of resources and conditions.

54.3 recap

An organism's life history is characterized by its lifetime pattern of growth, reproduction, and survival. All species have a characteristic life history strategy, which arises from genetic and environmental constraints on life history traits. Two extremes of life history strategies include species with high population growth rates (*r*-strategists) and species that persist at or near their carrying capacity (*K*-strategists). Most species fall along a continuum between these two strategies.

learning outcomes

You should be able to:

- Distinguish between the relative contributions of environment and genetics to life history traits in specific situations.
- Describe how and why life history trade-offs might arise in a species or population.
- Distinguish between *r*-strategists and *K*-strategists, and identify specific situations in which evolution might favor one strategy over the other.

1. Refer to [Figure 54.14](#).

- a. Does the change in life expectancy for humans over the past 175 years suggest a genetic or an environmental cause?
- b. Given your answer, are the large differences in human life span for Japan versus Angola, shown in [Figure 54.13](#), likely the result of genetic or environmental factors? Explain.

2. Why are species unable to maximize growth, reproduction, and survival? In other words, why are there life history trade-offs?

3. Refer to [Figures 54.11](#) and [54.12](#). What life history strategies characterize *Lobelia telekii* versus *L. keniensis*? How about guppies in high-predation versus low-predation stream sites?

For millennia, humans have tried to increase populations of desirable or useful species and reduce populations of species they consider undesirable. Such efforts are most successful if they are based on knowledge of how those populations grow and what determines their densities.

***connect the concepts** Constraints on optimality include genetic variation for evolution to act on, as well as the mediating effects of the physical and biological environment. Review [Key Concept 21.5](#).

***connect the concepts** Linked genes are inherited together. Genes can be linked if they occur on the same chromosome. Review [Key Concept 12.4](#).

54.4 Population Biology Can Be Used in Conserving and Managing Populations

If we want to manage other species—that is, to increase or decrease their populations—we need to understand their life histories and population dynamics. We turn now to how populations can be managed to our benefit.

focus your learning

Appropriate management and conservation of wild or commercial populations requires knowledge of their life history strategies and population dynamics.

Successful control of undesirable species, including biological control, relies on an understanding of population dynamics.

Thorough understanding of metapopulation dynamics can help prevent species extinction.

Management plans must take life history strategies into account

Knowing the life history strategy of a species can be helpful in managing populations of commercial value. The black rockfish (*Sebastes melanops*), an important game fish that lives off the Pacific coast of North America, provides one such example. Rockfish have an indeterminate growth pattern—they continue to grow throughout their lives. As in many other animals, the number of eggs a female rockfish produces is proportional to her size, so larger females produce more eggs than smaller females. In addition, older, larger females are better able to provision the eggs they produce with oil droplets, which provide energy to the newly hatched larvae, giving them a head start in life. Larvae from eggs with larger oil droplets, produced by larger females, grow faster and survive better than do larvae from eggs with smaller oil droplets. These life history traits have important implications for the management of rockfish populations.

Because fishermen prefer to catch big fish, intensive fishing off the Oregon coast from 1996 to 1999 reduced the average age of female rockfish from 9.5 to 6.5 years. Thus the females reproducing in 1999 were, on average, smaller than the females reproducing in 1996. This change decreased the average number of eggs produced by females and reduced the average growth rate of larvae by about 50 percent. This reduction in reproductive ability was linked to a decrease in the ability of the rockfish population to recover from intensive fishing. Maintaining productive populations of rockfish may require regulating the number or size of fish caught, the fishing season, and/or setting aside no-fishing zones where some females can be protected from fishing and allowed to grow to large sizes.

Management plans must be guided by the principles of population dynamics

If we look at a logistic growth curve (see [Figure 54.8](#)), we can see that the number of births tends to be highest when a population is well below its carrying capacity. Therefore if we wish to maximize the number of individuals that can be harvested from a population, we should manage the population so that it is far enough below the carrying capacity to have a high birth rate. Hunting and fishing regulations are established with this objective in mind.

Fish can, however, be overharvested, as illustrated by the story of the black rockfish. Many fish populations have been greatly reduced because so many individuals were harvested that the few surviving reproductive adults could not maintain the population. For example, Georges

Bank, off the northeast coast of North America—a source of cod, haddock, and other prime food fish—was exploited so heavily during the twentieth century that many fish stocks have been reduced to levels insufficient to support a commercial fishery ([Figure 54.16](#)). With fishing restrictions the haddock population has rebounded, but the cod population has not.

Figure 54.16 Overharvesting Can Reduce Fish Populations Harvests of cod and haddock on Georges Bank (map inset) have led to dramatic population declines of both species. Fishing regulations on haddock have allowed its stock to rebound enough to once again support a commercial fishery.

Many rapidly reproducing species can recover if **overharvesting** is stopped, but recovery is more difficult for slowly reproducing species. Just as they did with the humpback whale, twentieth-century whalers hunted the blue whale (*Balaenoptera musculus*), Earth's largest animal, nearly to extinction. These whales reproduce very slowly: they live up to 10 years before becoming reproductively mature, produce only one offspring at a time, and have long intervals between births. As opposed to humpback whales, however, blue whale populations have recovered more slowly.

Whether we want to manage the sizes of populations of desirable species for sustainable harvesting or of undesirable species for control purposes, the same principles apply. **Biological control** is the use of natural enemies (predators, parasites, or pathogens) to reduce the population density of an economically damaging species. In many cases the target species is a pest only because it has been introduced to a new area. Natural enemies used for biological control are often obtained from the native region of the pest species. Biological control became popular in the nineteenth century after an outbreak of cottony-cushion scale, an Australian insect that attacks citrus, appeared in citrus groves in California. A predaceous ladybeetle and a parasitic fly were then introduced from Australia. Within a year of their release, these insects brought the scales under control.

biological control The use of natural enemies (predators, parasites, or pathogens) to reduce the population density of an economically damaging (pest) species.

Sometimes, however, introduced natural enemies not only fail to have any effect on the pest they were imported to control but also, freed of their own enemies, become pests themselves.

This fact underlies the horror story of the cane toad (*Rhinella marina*) in Australia. This Central American toad was introduced to control cane beetles attacking Australian sugarcane fields. But Australian cane beetles stay high on the upper stalks of the plants; the toads could not reach that high, and thus had no effect on the beetle population. Unfortunately, they had massive effects on other species.

All stages of the *R. marina* life cycle are poisonous, and Australian reptiles (including snakes and lizards) and mammals that eat them usually die. With no enemies to limit their population growth, cane toads grow fast and outcompete native amphibian species for resources. The toads have spread from northern Australia down the east coast, where they threaten native frog species by preying on them as well as by competing with them. The Australian government is forced to spend millions of dollars in attempting to reduce their numbers.

Knowledge of metapopulation dynamics helps us conserve species

Ecologists have used information on metapopulation dynamics to conserve endangered species. We know from mathematical models that the risk of extinction for a species can depend on the number and size of its populations within a metapopulation, and on the rates of dispersal among them. In some metapopulations there are [source populations](#), which serve as a net source of individuals for [sink populations](#), which receive more immigrants than they produce. Thus, although some individual populations may undergo severe decline as a consequence of natural or human-caused factors, source populations within a metapopulation can serve to rescue them.

source populations Populations that serve as a net source of individuals to other populations within a metapopulation.

sink populations Populations that receive more immigrants from other populations within a metapopulation than they produce.

A dramatic example of such metapopulation dynamics is provided by Edith's checkerspot butterfly (*Euphydryas editha bayensis*). This endangered subspecies feeds on only two species of annual plants (California plantain and purple owl's clover) that are endemic to outcrops of serpentine rock on hills south of San Francisco. In 1960 Paul Ehrlich and his colleagues at Stanford University began studying a population of this butterfly in the nearby Jasper Ridge Biological Preserve and discovered that it was one of several populations within a large, very fragmented metapopulation ([Figure 54.17](#)).

Figure 54.17 A Metapopulation of Checkerspots The San Francisco Bay Area metapopulation of Edith's checkerspot butterfly is divided into several populations confined to patches of suitable habitat on serpentine rock outcrops that contain the food plants of the species. Arrows indicate colonization events.

Activity 54.5 Metapopulation Simulation www.Life11e.com/ac54.5

They followed all the populations over several years and found that they varied in size. During drought years, the butterfly populations declined in size because most of the host plants that the caterpillars relied on died early in the spring, before the caterpillars had a chance to eat them. A severe drought in 1975-1977 led to extinctions of some of the populations. One of the empty habitat patches was repopulated a few years later, most likely by individuals from the largest single population, Morgan Hill, which as late as 1989 contained several hundred thousand butterflies. In 1998, however, the Morgan Hill population, which had historically been the largest in the metapopulation, went extinct. Ehrlich and his colleagues examined 70 years of climate data for the region and concluded that increasing climate variation accounted for the extinction. They also concluded that without a large, stable source population to provide emigrants for recolonization, as the Morgan Hill population did during the 1970s drought, it is unlikely that any of the other populations, which are sink populations, will persist without human intervention.

54.4 recap

Efforts to manage populations are more likely to be successful if they are based on an understanding of life histories and population and metapopulation dynamics. Biological control is the use of natural enemies to reduce the population density of an economically

damaging species. Metapopulations can conserve endangered species if source populations, which supply a source of individuals to sink populations, can rescue those populations from extinction.

learning outcomes

You should be able to:

- Specify possible density-dependent approaches to controlling a population of undesirable organisms, and discuss the different results each approach would have.
- Analyze the importance of source and sink populations in a metapopulation in terms of their function in conserving a species from extinction.

1. Describe an effective strategy for recovering the population size of a desirable species that has a *K*-strategist life history.
2. Refer to [Figure 54.17](#)
 - a. Describe factors responsible for the metapopulation size of the Edith's checkerspot butterfly in the San Francisco Bay area.
 - b. Given the 1998 extinction of the Morgan Hill population, what is the likely fate of the metapopulation? Explain your answer.

▶ investigatinglife

What is the human population growth projected to be in the next century, and how will that affect population size?

You have seen that this question is highly dependent on the factors that ultimately control the number of births and deaths, or population growth, of humans over time. If the population growth rate projections are correct, there will be roughly 11 billion humans in 2100. Is 11 billion above the carrying capacity of humans? Estimates of the carrying capacity published in 1994 varied 10-fold: from less than 3 billion to 44 billion, with the median estimated at 12 billion. As opposed to the carrying capacities of other species, human carrying capacity depends on natural constraints important to all species, but also on individual and collective choices concerning the distribution of material goods, the use of technology, and the right to political, economic, and cultural freedoms. The number of people that can live on Earth will depend in part on how many will own cars, eat meat, or have air conditioning. For example, estimates suggest that if the carrying capacity values for the population in the United States were applied worldwide, Earth's carrying capacity would be limited to 1.2 billion. Compare this with the estimated values for India, where the worldwide carrying capacity could be extrapolated to 14 billion. Given that the current population size on Earth is 7.4 billion, it is clear that the vast majority of humans do not, and will not, experience the quality of life inherent to many in the United States.

Future directions

Some have argued that the number of people that can ultimately live on Earth will depend on the ability of humans to continue to expand their carrying capacity through technological innovations and greater efficiencies in food production and energy generation. These technological innovations will require that we increase food production and natural resource extraction without a heavy reliance on fossil fuels, which have a limited supply and adverse effects on the climate. Ultimately, to believe that no ceiling to human population size is inevitable defies what we know about natural populations.

► 54.1 Populations Show Dynamic Variation in Size over Space and Time

- Species are divided into groups of individuals, or populations, that can vary spatially across their geographic range. [Review Figure 54.1 A](#)
- A group of geographically isolated populations linked together by dispersal is known as a metapopulation. A species might consist of one or multiple metapopulations, depending on its geographic range. [Review Figures 54.1, 54.4](#)
- All populations fluctuate in size over time due to the physical environment, biological interactions, and dispersal. [Review Figure 54.2](#)
- Ecologists use a variety of approaches to estimate population sizes, including full censuses, surveys using quadrats or transects, mark-recapture methods, and DNA analysis. [Review Figure 54.5, Animation 54.1](#)

► 54.2 Population Growth Describes the Change in Population Size over Time

- **Population growth** is the change in population size over time, as reflected by the number of births, deaths, and migrants in and out of the population. [Review Equation 54.1](#)
- **Exponential growth** occurs when the rate of change in population size is constant over time. [Review Figure 54.6, Activity 54.1](#)
- **Logistic growth** occurs when resources are limited, slowing growth to a population's maximum size (carrying capacity). [Review Focus: Key Figure 54.8, Activities 54.2, 54.3](#)
- Factors limiting population growth can be **density-dependent** when intraspecific competition between individuals affects population growth. **Density-independent** factors are those that act independently of the population density, such as physical conditions.
- **Life tables** summarize how survival and fecundity vary with the age, size, or sex of individuals within a population, and incorporate how these demographic events affect population growth. [Review Table 54.1](#)
- Species have different types of **survivorship curves** that reflect mortality patterns over time. [Review Figure 54.9, Activity 54.4](#)

► 54.3 Life History Is the Lifetime Pattern of Growth, Reproduction, and Survival

- **Life history strategies** are characterized by lifetime patterns of growth, reproduction, and survival, and can vary at the species and population levels. [Review Figure 54.10](#)
- Life history **trade-offs** arise from genetic and environmental constraints on optimal growth, reproduction, and survival.
- Extremes in life history strategies of species allow for high growth rates (**r-strategists**) or for persistence at or near the carrying capacity (**K-strategists**), but most species fall along a continuum between these two strategies. [Review Figure 54.15](#)

► 54.4 Population Biology Can Be Used in Conserving and Managing Populations

- Efforts to manage populations are more likely to be successful if they are based on an understanding of life histories and population and metapopulation dynamics.
- **Biological control** is the use of natural enemies to reduce the population density of an economically damaging species.
- Metapopulations can conserve endangered species if **source populations**, which serve as a source of individuals to **sink populations**, can rescue those populations from extinction. Review [Figure 54.17](#), [Activity 54.5](#)

Review

- 4.2 Life tables help predict how age-related survival and reproduction affect population growth.
- 4.4 Appropriate management and conservation of wild or commercial populations requires knowledge of their life history strategies and population dynamics.

Original Paper: Simpfendorfer, C. A. 2005. Demographic models: Life tables, matrix models and rebound potential. In J. A. Musick, and R. Bonfil, eds. *Management techniques for elasmobranch fishes*. FAO Fisheries Technical Paper 474: 143-153.

Many temperate shark species grow slowly, have a long life span, mature late, and produce few young. By contrast, the tropical Australian sharpnose shark is fast-growing, short-lived, and matures early. Because of its small size, it is not routinely fished, but it is frequently caught as bycatch in gillnet fisheries for other species.

Management decisions about endangered shark populations require knowledge of how their population growth rates respond to mortality events such as predation, disease, and fishing (including bycatch mortality). Life tables can be used to predict how age-related survival and reproduction affect population growth rates of shark populations.

The table is a static life table for the Australian sharpnose shark. It was constructed from shark catch data during a single fishing season (only female individuals were used in the analysis). The table is composed of survivorship (l_x : the number of females that have survived within each age class) and fecundity (m_x : the number of females born per adult female shark within each age class). Note that survivorship and fecundity at age 0 are for individuals just born into the population.

Age (x)	Survivorship of females (l_x)	Fecundity of female offspring (m_x)	$l_x m_x$	$x l_x m_x$
0	1	0		
1	0.32	1.98		
2	0.19	2.59		
3	0.11	2.81		
4	0.06	2.89		
5	0.03	2.92		
6	0.02	2.93		
7	0.01	2.93		
8	0.005	2.93		
9	0.003	2.93		
10	0.002	0		

Questions

1. Complete the fourth column of the table by calculating $l_x m_x$ for each age class (x) of the population. Then, calculate the net re-productive rate (R_0) for the population, and explain what this value represents.
2. Given the value of R_0 for the population, can you determine whether the shark population is increasing, decreasing, or not changing in size? Explain your answer.
3. Complete the final column of the life table by calculating $x l_x m_x$ for each age class (x) of the population. Then, calculate the generation time, G , for the population.

1. Using previous calculations of R_0 and G , calculate an estimate of r , the per capita growth rate of the population.
2. Consider the life history differences between the Australian sharpnose shark versus the larger temperate sharks. Which shark populations do you think will have a higher r value? Given fishing pressures and life history characteristics, which shark populations do you think have a greater chance of being overfished? Explain your answer.

investigatinglife

The Lionfish King

The coral reefs surrounding the Bahamas have endured the effects of human activity for centuries, but for the last two decades they have faced a threat unlike any other—the invasion of two species of beautiful but highly destructive lionfishes (*Pterois volitans* and *P. miles*). Lionfishes, first spotted off the coast of Florida in the mid-1980s, are native to the Indo-Pacific region and are popular aquarium fishes. How they came to their new habitats is uncertain, but DNA evidence suggests that they were released into the Atlantic Ocean by unsuspecting aquarium owners. Over the last two decades, lionfish populations have thrived, successfully invading the Western Atlantic, the Caribbean and Gulf of Mexico, and now as far south as Brazil. The invasion has progressed to the point that the density of lionfish in the Atlantic is greater than in their native Pacific range; in some locations, 450 lionfish per hectare (2.5 acres) have been recorded.

The invasion of marine habitats by fish predators is extremely rare. What, then, allows lionfishes to be so successful? Part of their success has to do with their ability to tolerate a variety of tropical and subtropical temperatures and salinities—from the warm waters of shallow reefs, mangroves, and sea-grass beds to the colder waters of deep reefs and offshore currents. But the real story lies in their interactions with other species—they are dominant predators and competitors in their introduced range. A survey of lionfish populations at nine sites off the coast of the Bahamas showed that their abundance increased 2.5-fold from 2008 to 2010, despite the presence of 16 species of similar native competitor fish (which declined by 44% during that period). Gut analyses of lionfish showed that they are voracious generalist predators; the increase in lionfish abundance coincided with a 65 percent decline in small-bodied coral-reef fish representing 42 different species. Other studies have shown similar results, reinforcing the notion that lionfishes may be among the most damaging marine invaders known.

Explaining the success and devastating impact of these invaders requires an understanding of the ecology and evolution of species interactions, the subject of this chapter. We will return to the example of the lionfishes' extraordinary success in capturing their prey at the end of this chapter.

QA Why are small coral-reef fish species so vulnerable to lionfish predation, and what can be done about it?

55.1 Species Interactions Vary in Direction and Strength across a Continuum

One of life's certainties is that every species on Earth will encounter and interact with other species. These interactions have consequences that affect not only individuals but populations, and ultimately the distribution and abundance of species. Over the long term, they can lead to evolutionary change in one or more of the interacting species. For ease of description, we will focus on two-way relationships, such as one species eating another or two species competing for the same limiting resources. In reality, species interact with multiple species as part of an integrated ecological community. We will explore these community dynamics in [Chapter 56](#).

focus your learning

Species interactions are classified by the effect (positive, negative, or neutral) they have on one another.

Broad categories of species interactions are predation, competition, positive interactions, and amensalism.

Species interactions are often dynamic and asymmetrical; that is, species have unequal effects on one another.

Some species interactions can affect the survival or reproduction of individuals in interacting populations, resulting in genetic and evolutionary changes.

Ecologists characterize species interactions based on the effects species have on each other — positive (+), negative (–), or neutral (0) —and whether that effect is **trophic** (feeding) or not (**Focus: Key Figure 55.1**). In addition, species interactions may include a **symbiosis**, a condition in which one of the species lives in or on the other species. As you will see, symbioses can occur whether the interaction is positive or negative. Four broad categories into which species interactions fall are predation, competition, positive interactions, and amensalism.

trophic [Gk. *trophes*: nourishment] The feeding relationship between two or more species.

symbiosis (sim' bee oh' sis) [Gk. *sym*: together + *bios*: living] The living together of two or more species in a prolonged and intimate relationship.

Commensalism	+	0
Amensalism	-	0

(B)

Parasitism, Predation, Mutualism

The buffalo's hide is infested with parasitic ticks. Oxpecker birds eat the ticks, to the mutual benefit of the birds and the buffalo.

Herbivory

The African buffalo feeds on the grasses of the savanna.

Amensalism, Commensalism

The large mammal unwittingly destroys insects and their nests. The white cattle egrets feed on insects disturbed by the buffalo's passage.

Predation

Carnivores such as wolves hunt and kill herbivorous mammals.

Competition

The grizzly bear is attempting to take over the wolves' kill.

Figure 55.1 Types of Species Interactions Interactions among species can be grouped into categories based on whether their influence on each of the interacting species is positive (+), negative (-), or neutral (0). Species

interactions are an everyday occurrence within communities.

Q: Are any of the species interactions featured in the photos trophic or symbiotic? If so, which ones?

Activity 55.1 **Ecological Interactions** www.Life11e.com/ac55.1

Predation is a trophic interaction in which an individual of one species (a **predator**) kills and/or consumes individuals (or parts of individuals) of another species (its **prey**). Predation includes **carnivory**, in which the predator and prey are both animals; **herbivory**, in which the predator is an animal and the prey is a plant or algae; and **parasitism**, in which the predator (a **parasite**) lives symbiotically on or in the prey (its **host**) and consumes only certain tissues without necessarily killing the host. Some parasites are pathogens that cause disease in their hosts.

Competition is a nontrophic interaction in which two or more species overlap in the use of at least some of the same required limiting resources, negatively affecting their growth, reproduction, and/or survival. Competition can occur under a variety of circumstances: between predators that depend on the same prey species (such as you saw in the lionfish example), between herbivores that feed on the same host plant, or between pathogenic microbes attacking the same host. The limiting resource need not be food; species may compete for water, space, nesting sites, or even (in the case of plants) sunlight.

Positive interactions (also known as **facilitations**) are trophic or nontrophic interactions in which at least one species benefits from the interaction and none are harmed. Positive interactions include **mutualisms**, in which both species benefit from the interaction, sometimes in a highly dependent and symbiotic manner. **Commensalism** is a type of positive interaction in which one participant benefits but the other is unaffected; it includes a wide range of interactions that typically encompass the provisioning of food and habitat that improve conditions for the commensal organism.

Amensalisms occur when one participant is harmed but the other is not affected. An example is a herd of elephants moving through a forest and crushing plants; the elephants are not affected by this event, but the plants clearly are. Another example includes small understory plants that grow under trees. The understory plants are deprived of light but likely have no effect on the trees.

predation A trophic or feeding interaction in which an individual of one species (a predator) kills and/or consumes individuals (or parts of individuals) of another species (its prey).

predator An organism that kills and/or consumes individuals (or parts of individuals) of another species (its prey).

prey [L. *praeda*: booty] An organism killed and/or consumed by a predator as an energy source.

carnivory An act of predation in which the predator and prey are both animals. (Contrast with herbivory, parasitism, or omnivory).

herbivory (ur' bi vore) [L. *herba*: plant + *vorare*: to devour] An act of predation in which the

predator is animal and the prey is a plant or algae. (Contrast with carnivory, parasitism, omnivory.)

parasitism An act of predation in which the predator (a parasite) lives symbiotically on or in the prey (its host) and consumes only certain tissues without necessarily killing the host. (Contrast with carnivory, herbivory, omnivory.)

parasite [Gk. *parasitos*: one who eats at another's table] An organism that kills and/or consumes parts of an organism much larger than itself (known as its host). Parasites sometimes, but not always, kill their host.

host An organism that harbors a parasite or symbiont and provides it with nourishment.

competition A nontrophic interaction in which two or more species overlap in the use of at least some of the same required limiting resources, negatively affecting their growth, reproduction, and/or survival. (Contrast with amensalism, commensalism, mutualism.)

positive interaction Trophic or nontrophic interaction between two species in which one or both species benefit and neither is harmed. (See *also* facilitation, mutualism, commensalism.)

facilitation A positive interaction. See positive interaction.

mutualism A type of positive interaction in which both species benefit from the interaction, sometimes in a highly dependent and symbiotic manner. (Contrast with amensalism, commensalism, competition.)

commensalism [L. *com*: together + *mensa*: table] A type of positive interaction in which one species benefits from the interaction while the other is unaffected. (Contrast with amensalism, competition, mutualism.)

amensalism A type of interaction in which one species is harmed and the other is unaffected. (Contrast with competition, commensalism, mutualism.)

Species interactions are not always clear-cut

Although ecologists find it useful to classify interactions among species into a few basic categories, the boundaries between groupings are not always clear. In reality, the interaction categories described in this section are part of a continuum in how strongly each species affects the other ([Figure 55.2](#)). The continuum is a consequence of the variable strength in species interactions and their asymmetrical nature. For example, competition between the native Eurasian red squirrel (*Sciurus vulgaris*) and the non-native eastern gray squirrel (*S. carolinensis*) in the United Kingdom is highly asymmetrical, with the gray squirrel having a much stronger effect on the red squirrel than vice versa. This asymmetry is the result of the gray squirrel's ability to better obtain limiting food resources, particularly oak acorns, causing the red squirrel's population sizes to decline. The red squirrel is also declining, because of a fatal disease spread by the gray squirrel.

Figure 55.2 A Continuum of Competitive Effects Species interactions, such as competition, vary in their strength (represented by the thickness of the bars) and symmetry depending on the effects of one species on the other species. Amensalism occurs when one species suffers a negative effect from the interaction but the other species is not affected.

Q: Suppose the Eurasian red squirrel described in the text is species 1 and the eastern gray squirrel is species 2. Indicate which pairs of interactions between species 1 and 2 would best represent their relationship.

Species interactions can be difficult to classify because of the different ways in which interactions affect particular species. For example, sea anemones in the Pacific Ocean sting and eat small fish, but a select few fish species (mostly in the genus *Amphiprion*) live within the tentacles of sea anemones and are unaffected by their stings. Safe from its predators, an anemonefish moves freely among the stinging tentacles to scavenge the leftovers of the anemone (**Figure 55.3**).

Figure 55.3 Interactions between Species Are Not Always Clear—Cut Ecologists long believed that the relationship between sea anemones and anemonefish was a commensalism: that the fish, by living among the anemone's stinging tentacles, gained protection from its predators. But it could also be considered a mutualism, if the fish's feces provide the anemone with beneficial nutrients.

Amphiprion percula

Anemonefish must acclimate to the anemone's venom, and the anemone, in turn, must acclimate to the fish. The acclimation process appears to involve a change in the mucus coat of the fish; wiping off the mucus of an acclimated fish results in immediate stinging, whereas anemones do not sting fish with intact mucus. The benefits of this relationship to the anemonefish are clear: it escapes its own predators by hiding behind the anemone's stinging tentacles, and it has no need to forage widely for food. But does the anemone benefit from the association? By defecating while in residence, the anemonefish may provide nitrogen-rich nutrients to the anemone. However, the fish may occasionally steal the anemone's prey, which has a negative effect on the anemone's fitness. Thus the net outcome of the interaction depends on the ecological circumstances under which it occurs, including the influence of other species and the existing physical conditions.

Some interactions result in evolutionary change in the species involved

All types of interactions have the potential to influence the population sizes of interacting species. By contributing to the differential survival or reproduction of individuals with different traits, they can also alter genotype frequencies within the interacting populations over time. Thus these interactions have both ecological consequences, as when they affect the distribution and

abundance of a species, and evolutionary consequences, as when they lead to evolutionary change. Darwin observed that evolutionary change occurs not only in response to physical conditions, as described in [Chapter 53](#), but also in response to interactions among species. In his introduction to *On the Origin of Species*, Darwin pointed out that woodpeckers have feet, tails, beaks, and tongues “admirably adapted to catch insects under the bark of trees” as a result of their long-standing interactions with their insect prey.

While abiotic factors also act as agents of selection, they differ in a fundamental way from biotic agents of selection in that they do not themselves undergo change as a result of the interaction. Snow and ice do not become more deadly as a result of encountering cold-resistant organisms, but predators can, over evolutionary time, become swifter, more powerful, or more efficient at capturing their prey. In response, prey species may become swifter, tougher, less conspicuous, or more poisonous, all of which decrease their likelihood of being consumed. This back and forth evolutionary response between interacting species is known as [coevolution](#).

coevolution Evolutionary process in which an adaptation in one species leads to the evolution of an adaptation in a species with which it interacts.

The types of interactions most likely to lead to coevolution are those that occur predictably and with high frequency over time and that have a strong effect on the fitness of species. Thus species involved in amensal and commensal interactions are less likely to experience coevolutionary change as a result of the interaction than are species involved in predatory, competitive, and mutualistic interactions.

55.1 recap

Species interactions may be classified into four basic categories: predation (a trophic interaction in which a predator kills and/or consumes its prey, or part of its prey), competition (a nontrophic interaction in which species use some of the same limiting resources and have negative effects on one another), positive interactions (a trophic or nontrophic interaction in which at least one species benefits from the interaction and none are harmed) or amensalism (a nontrophic interaction in which one species is harmed but the other is not affected). Species interactions are not always clear-cut but instead fall along a continuum in which species vary in how strongly they affect one other. Some species interactions result in evolutionary change.

learning outcomes

You should be able to:

- Use examples to distinguish among predation, competition, positive interactions (mutualism and commensalism), and amensalism.
- Give examples of species interactions in which the responses of two species are asymmetrical, and evaluate possible reasons for the asymmetry.
- Compare biotic and abiotic factors as agents of natural selection and evolution.

1. Classify each of the following species interactions as carnivory, herbivory, parasitism, competition, amensalism, mutualism, or commensalism.
 - a. Leafcutter ants harvest and transport leaf fragments to their nests, where the vegetation will support fungus, which the ants consume.

- b. Elephant seals lie on rocks, crushing and detaching algae underneath them.
 - c. Head lice inhabit the human scalp and feed on blood.
 - d. Wolves and cougars both prey on the same deer population, which is limiting to both predators.
2. Name some conditions that can modify or change the outcome of a two species interaction.
3. Do you think the interactions between lionfishes and their fish prey in the Atlantic Ocean have resulted in evolutionary change for the prey? Explain.

Trophic interactions are critical to life on Earth. As a result, the variety of ways that heterotrophic organisms acquire food plays a critical role in the success of every species on Earth. In the next section we will consider how predation influences the ecology and evolution of both predator and prey species.

55.2 Predation Is a Trophic Interaction in which Predators Benefit and Prey Are Harmed

Predator–prey interactions are probably the most familiar, and perhaps the most dramatic, type of species interaction. Even though carnivory, herbivory, and parasitism all involve the simple interaction of one species eating another species, they often defy categorization. For example, a carnivore might sometimes function like an herbivore by eating berries and roots, or an insect might be considered an herbivore or a parasite if it spends its entire life feeding on a single tree. In addition, predators can differ considerably in the ways they affect their prey's population dynamics if the prey species is not killed in the process. Despite these complications, we will explore predation by considering carnivory, herbivory, and parasitism separately. We will end by drawing on some generalities regarding population and community consequences of predation.

focus your learning

Prey have evolved many strategies to avoid being captured, including escape, avoiding detection, chemical defenses, warning signals, and mimicry.

Plants and herbivores have developed reciprocal adaptations to counter their effects on one another.

Parasites are abundant and have highly varied effects on their hosts.

Coupled predator–prey cycles greatly influence the populations of both species and the communities in which they reside.

Carnivory results in a range of capture and avoidance mechanisms

Given that carnivores almost always kill the prey they consume, the interests of both predator and prey are at stake: the best strategy for carnivores is to maximize their ability to capture and consume prey while the best strategy for prey is to minimize the likelihood of being eaten. We first consider the strategies carnivores use to obtain food and then examine how prey avoid being eaten.

What strategies do carnivores use to obtain food? The success of carnivores depends on balancing the cost of pursuing, capturing, and handling prey against the energetic benefit of consuming them, as discussed in [Key Concept 52.4](#). At one extreme, carnivores use strength and swiftness to actively search for and capture high-quality prey. The “active pursuit” strategy is used by predators of all sizes: both Orca whales pursuing gray whales and foxes pursuing birds are fast, powerful predators and are equipped with strong jaws ([Figure 55.4A](#)). At the other extreme, an ability to look inconspicuous allows the stealthy predator to ambush prey unlucky enough to pass its way ([Figure 55.4B](#)). Various other predation strategies have evolved in predators that are smaller than their prey. For example, the jaws of some snakes open wide enough to allow them to swallow prey larger than their head. The tiny short-tailed shrew, among the smallest mammalian predators, produces venomous saliva that paralyzes earthworms and snails but also prey much larger than itself, including mice and small birds.

(A) *Vulpes vulpes fulva*

(B) *Ceratophrys* sp.

Figure 55.4 Active Searcher or Stealthy Ambusher Predators can be **(A)** active searchers such as the swift and strong fox or **(B)** stealthy ambushers such as the seemingly inconspicuous wide mouth frog.

Prey species have in turn developed a variety of defenses against predators. Some escape from predators simply by flying or running away. Others have morphological defenses; tough skin, shells, spines, or hair can foil even a determined predator ([Figure 55.5A](#)). Various other defenses that prey have evolved to avoid capture are described below.

(A) *Hystrix cristata*

(B) *Typophyllum* sp.

(C) *Chromodoris* sp.

(D) *Dendrobates reticulatus*

Figure 55.5 Adaptations to Avoid Being Eaten (A) Porcupines have a coat of sharp spines, or quills, that protect them from predators. (B) Birds searching for insect prey are likely to bypass a katydid that looks like a partially eaten leaf. (C) Nudibranchs (sea slugs) are mollusks without protective shells that may possess stinging nematocysts acquired from their hydrozoan prey. (D) Poison dart frogs of Central and South America sequester highly toxic chemicals in their brightly colored skin.

AVOIDING DETECTION

Prey species can often escape predators by hiding. One form of hiding is camouflage, also known as crypsis. Crypsis allows species to resemble objects that their predators consider inedible. The katydid in [Figure 55.5B](#), for example, looks very much like a dead leaf, even down to the likeness of a spot of fungal decay.

Because the vision of many types of predators is adapted to spot moving prey, many prey species simply stop moving if they are being pursued. “Playing possum,” a term that is sometimes applied to this strategy, refers to the ability of opossums to simulate death.

CHEMICAL DEFENSES

Many animals use chemical defenses to escape or repel their predators. Chemical defenses are generally used by animal prey that are small, weak, sessile, or otherwise unprotected. Many insects produce sprays, oozes, or froths when attacked. Bombardier beetles, for example, eject a hot (100 °C) noxious chemical spray from the tip of their abdomen that can be fatal to attacking insects.

Media Clip 55.1 Bombardier Beetle Sprays Its Enemies www.Life11e.com/mc55.1

Activity 55.2 Coevolution Simulation www.Life11e.com/ac55.2

Activity 55.3 Predator–prey System Simulation www.Life11e.com/ac55.3

Predators may evolve adaptations to overcome their prey's chemical defenses, as you saw in the case of the rough-skinned newt and the garter snakes that have become insensitive to the newt's protective toxin (see Figure 21.20). Some predators ingest and sequester their prey's defensive chemicals and use them as defenses against their own predators. For example, some sea slug species incorporate toxic chemicals from their sponge prey, whereas others, which feed on hydrozoans, incorporate the stinging cells into their own bodies ([Figure 55.5C](#)). Likewise, poison dart frogs from Central and South America sequester toxins from their prey, which include ants, mites, and other small invertebrates ([Figure 55.5D](#)).

WARNING SIGNALS

Some prey species that defend themselves with toxic chemicals advertise that fact with a [warning signal](#). Warning signals may be visual (many toxic species are brightly colored) or acoustical (the rattlesnake's warning rattle, for example), depending on what sensory cues their predators use to find prey.

warning signal A visual or acoustical defense mechanism used by prey species to advertise to predators that they may be toxic.

Many toxic prey, such as the nudibranchs and frogs in [Figures 55.5C](#) and [D](#), sport bright colors or striking patterns to protect themselves against visually orienting predators. Such warning coloration increases the probability that a predator will learn to recognize and avoid the toxic species. Some vertebrate predators that rely on visual cues can learn quickly to associate certain color patterns with an unpleasant feeding experience.

MIMICRY SYSTEMS

There are two general types of mimicry systems that have evolved repeatedly in nature: Batesian mimicry and Müllerian mimicry. In [Batesian mimicry](#), a benign, edible species (the mimic) closely resembles a dangerous, toxic species (the model). The mimic benefits from the avoidance behavior of predators of the model ([Figure 55.6A](#)). In [Müllerian mimicry](#), two or more species converge on a common warning signal; all benefit from providing a stronger recognition signal to predators. Many of the Neotropical longwing butterflies (*Heliconius*), which as caterpillars feed on toxic passionflower plants and incorporate the plant toxins into their bodies, are Müllerian mimics. *Heliconius* species living together in a particular geographic region are likely to have similar coloration and share a common warning pattern ([Figure 55.6B](#)). Genome sequencing of *Heliconius* Müllerian mimics has identified one gene, *optix*, that codes for a transcription factor that can, by changing gene expression patterns, create the same color patterns in *Heliconius* species that are not very closely related.

Batesian mimicry The convergence in appearance of an edible species (mimic) with an unpalatable species (model).

Müllerian mimicry Convergence in appearance of two or more unpalatable species.

(A) Batesian mimics

(B) Müllerian mimics

Figure 55.6 Truth in Labeling? (A) Batesian mimics are vulnerable species that gain protection by mimicking the warning signals of dangerous species. The appearance of the harmless blenny species *Petrosirtes breviceps* closely resembles that of the fanged striped blenny, which possesses a pair of grooved fangs with associated venom glands. (B) The shared warning coloration of Müllerian mimics is an honest advertisement of their toxicity. As caterpillars, all of the longwing butterflies (genus *Heliconius*) of South America feed on toxic passionflower plants and incorporate the toxins into their adult bodies. The *Heliconius* species living together in a particular region have similar warning coloration.

BEHAVIORAL MECHANISMS

Prey often use behavioral mechanisms to avoid predation. For example, as you saw in [Key Concept 52.6](#) and [Figure 52.21](#), group behaviors such as flocking and alarm vocalizations can provide protection from predators. In the lionfish example introduced in the chapter opening story, the evolutionary change in behavior that predator and prey may experience has not yet had time to develop. In [Investigating Life: The Lionfish King](#) we describe research showing that the small reef-fish prey of lionfishes are likely experiencing a novel predatory behavior not previously encountered, and thus may be defenseless in the face of lionfish predation. Lionfishes slowly approach their prey and direct jets of water toward them. Confused or distracted by the jets, the prey are often taken by headfirst capture. The highly efficient predatory behavior of lionfishes doubtless contributes to their success as invasive species in tropical Western Atlantic and Caribbean coral reefs.

experiment

Original Paper: Albins, M. A. and P. J. Lyons. 2012. Invasive red lionfish *Pterois volitans* blow directed jets of water at prey fish. *Marine Ecology Progress Series* 448: 1–5.

Mark Albins and his colleagues asked what feeding behaviors the invasive lionfish *Pterois volitans* might use to be a successful predator on Atlantic and Caribbean coral-reef fish. They conducted field observations of lionfish feeding on small reef fish and noticed that lionfish typically face their prey, flaring their pectoral fins and moving very slowly within striking distance of the prey. During the approach, lionfish produced a strong, pulsed jet of water from their mouths and directed it toward the prey. To investigate this novel feeding behavior, Albins and his colleagues conducted feeding trials on lionfish and native goby prey.

HYPOTHESIS▶ The novel feeding method of lionfish—in which jets of water are directed at their prey—disorients prey, allowing for easier headfirst capture.

METHOD

1. Using hand nets, capture lionfish and two species of native goby prey (*Coryphopterus glaucofraenum* and *Gnatholepis thompsoni*) from coral reefs and sea-grass beds in the Bahamas.
2. Acclimate lionfish and gobies to a flow-through aquarium and film their feeding behavior using a digital video camera.
3. Present lionfish with gobies in two ways: (1) release lionfish into an open aquarium setting containing the gobies, and (2) release lionfish into an aquarium that holds the gobies in transparent containers so the lionfish can see but not consume them.
4. Use a glass pipette to release food-grade dye in front of the lionfish to visualize the movement of water around its mouth.
5. Examine digital videos of all feeding trials to measure characteristics of water jets and response of the prey.

RESULTS

In all of the open aquarium trials, lionfish produced directed water jets at goby prey. Seven of the eight trials resulted in headfirst strikes. In the container trials, the lionfish produced an average of 18 water-jet pulses before striking at the prey. The maximum distance from the mouth of the lionfish that a visible jet-front reached was 10 cm.

CONCLUSION▶ What would you conclude about the feeding behavior of lionfishes and the responses of prey from the Atlantic Ocean versus the Pacific Ocean? Explore this question in the following work with the data exercise.

work with the data

In addition to the aquarium experiments, the researchers conducted field observations of the feeding behavior of lionfishes in different locations—their native Pacific Ocean and their non-native Atlantic Ocean. They found that, in the Atlantic Ocean, most successful captures by lionfishes did not require them to blow jets of water at their prey (only 18 percent of the captures involved this behavior). However, in the Pacific Ocean, they found that 56 percent of successful captures by lionfishes involved them blowing jets of water at their prey. The researchers also reported that an extensive literature search showed that blowing jets of water at prey appears to be unique to lionfishes.

QUESTIONS

1. Refer to Method step 3 in the experiment. Why do you suppose the researchers conducted lionfish aquarium feeding trials with free-swimming fish prey? Alternatively, what did the containers containing the fish prey afford the researchers?
2. Given what you know about the feeding behavior of lionfishes, would you expect them to produce more or fewer water jets to capture fish prey in the Atlantic Ocean compared with the Pacific Ocean? Would the distance the water jet had to travel be shorter or longer for the Atlantic Ocean prey compared with the Pacific Ocean prey?
3. Based on all the lionfish feeding behavior information presented here, what is the most plausible hypothesis to explain why lionfishes are such effective predators on coral-reef fishes in the Atlantic Ocean compared with the Pacific Ocean?

A similar **work with the data** exercise may be assigned in **LaunchPad**.

Herbivory is a widespread but specialized interaction

Herbivory is a widespread interaction, with the vast majority of herbivores being insects. Of those herbivorous insects, more than 90 percent are specialists that feed on just one or a few, often taxonomically related, plant species. Generalist herbivores, in contrast, feed on as many as hundreds of unrelated plant species. Vertebrate herbivores are usually generalists; a cow grazing in a pasture, for example, can consume many different plant species in a single afternoon. There are exceptions to this pattern, however. Australian koalas famously feed exclusively on the foliage of eucalyptus trees, and the diet of giant pandas is made up almost entirely of bamboo.

Herbivores, particularly insects, generally consume only parts of their food plants and usually

do not kill them. In most natural ecosystems, insects rarely remove more than a small percentage of the plant biomass. For that reason, some ecologists have questioned the ability of herbivores to exert strong selection pressure on plant traits. Mortality is not, however, the only form of selection that leads to evolutionary change; herbivores can reduce plant fitness if the plants they attack produce fewer offspring.

PLANT DEFENSES AGAINST HERBIVORES

Plant chemistry is one of the principal defense mechanisms against herbivores. Plants in the mustard family (Brassicaceae) offer just one example of the strategy of producing secondary metabolites as a mechanism to reduce herbivory. The amazing variety of secondary metabolites produced by plants to defend themselves against herbivores is considered in [Key Concept 38.2](#).

Some plants and algae protect themselves by being physically difficult to eat. For example, thorns and spines are highly effective deterrents to browsing vertebrate herbivores. Coralline algae contain calcium carbonate within their tissues, which deters many marine herbivores. An exception is some sea urchin species that have powerful articulated jaws and teeth and long coiling guts that can process less nutritious chalky tissue.

RECIPROCAL ADAPTATIONS IN HERBIVORES AND PLANTS

A spectacular variety of adaptations to plant defenses has evolved in herbivores. Many herbivores circumvent plant defenses by behavioral means. For example, the secondary metabolites produced by a plant called St. John's wort (*Hypericum perforatum*) require exposure to sunlight for optimal toxicity, so some insects that feed on this plant roll its leaves into a light-impervious cylinder and feed in comfort in the dark. Large herbivores such as deer and horses graze on a wide variety of plant species, minimizing their exposure to any particular defensive chemical. Long-lived and with relatively good memories, they can learn to avoid plants with an unpleasant taste.

Unlike large mammalian herbivores, caterpillars and many other insect herbivores may spend their entire lives feeding on a single individual plant. Such exclusive diets are associated with highly specialized detoxification systems. The diamondback moth caterpillar eats plants in the cabbage family, which are rich in toxic mustard oil glycosides. In its gut is an enzyme that breaks down the glycosides into harmless by-products.

Some herbivores take resistance a step further by storing, or sequestering, plant toxins in specialized organs or tissues that are insensitive to those toxins. This strategy also makes the sequestered chemicals available for defense against the herbivores' own enemies. The caterpillar of the monarch butterfly, for example, is insensitive to the neurotoxic glycosides in its milkweed host plants, but most of its enemies, including insect-eating birds, cannot tolerate these compounds.

Most parasites specialize on hosts, and most hosts house many species of parasites

Parasitism is an interaction in which a predator (a parasite) lives on or in the prey (its host) and consumes only certain tissues. Many parasite—host relationships are symbiotic. Effects of parasite—host interactions can vary dramatically in magnitude, from having weak effects to causing the death of the host. While parasites typically feed on only one or a few host species, hosts typically house many species of parasites ([Figure 55.7](#)). Parasites can also have their own parasites. This specialization helps explain why there are so many parasite species; it is estimated that roughly 50 percent of the species on Earth are parasites.

Figure 55.7 Why Are There So Many Parasites? It is estimated that roughly 50 percent of the species on Earth are parasites. Most parasites specialize on host species, most host species have multiple parasite species, and most parasites have their own parasites. This specialization may help explain why there are so many species of parasites.

Parasites can be classified as [microparasites](#), which include viruses, bacteria, and protists, or [macroparasites](#), which are larger and include such groups as worms and insects.

microparasites Parasite species too small to be seen with the naked eye, such as viruses, bacteria, protists, and fungi. (Compare with macroparasites.)

macroparasites Relatively large parasite species, such as arthropods and worms. (Compare with microparasites.)

MICROPARASITES

Microparasites are many orders of magnitude smaller than their hosts and generally live and reproduce inside their hosts. Multiple generations may reside within a single individual, and a host may harbor thousands or millions of them. Many microparasites, in the process of acquiring nutrients at the expense of their host, cause symptoms of disease and thus are considered pathogens. Host mechanisms that can limit pathogen proliferation include the immune system in animals (see [Chapter 41](#)) and biochemical defenses in plants (see [Key Concept 38.3](#)).

Just as with other predator—prey interactions, hosts and pathogens can place strong selective pressure on one another. If a pathogen strain is to persist in a host population, the pathogens must continually infect new host individuals. A less deadly strain that kills a smaller

proportion of host individuals may be able to infect a larger number of new hosts. Thus pathogen and host may reach a state of coexistence as increased host resistance (ability to withstand the effects of a pathogen) and decreased pathogen virulence (ability to cause disease) evolve. Yet new virulent strains may also arise, reminding us that evolution is constantly occurring.

An example of the complex interactions between host and pathogen comes from Australia, where the myxoma virus was introduced to control the exploding population of European rabbits (*Oryctolagus cuniculus*), which were devastating the rangeland vegetation used by cattle and sheep. The virus, which is transmitted by mosquitos, causes infections and blindness in rabbits, eventually leading to starvation and death. After the introduction of the virus in 1950, 99.8 percent of infected rabbits died. Millions of rabbits died over the following decades, but the rabbits slowly evolved resistance to the virus. The virus is still used to control rabbit populations, but this requires introducing new, more lethal strains of the virus to ultimately be effective.

MACROPARASITES

While microparasites generally live and reproduce inside their hosts, macroparasites are not always intimately associated with their hosts. Macroparasites rarely cause the same kinds of disease symptoms that pathogenic microparasites cause, but they may nevertheless affect host survival and reproduction and can thereby act as agents of selection on their hosts.

Ectoparasites are macroparasites that live outside the bodies of their hosts. **Endoparasites**, such as the tapeworms described in [Key Concept 30.4](#), are macroparasites that spend at least part of their life cycle inside the bodies of their hosts.

ectoparasite A parasite that lives on the surface of its host organism. (Compare with endoparasite.)

endoparasite A parasite that lives inside the body of its host organism. (Compare with ectoparasite.)

Some ectoparasites, such as leeches and mosquitoes, are only casually associated with their hosts, interacting with them just long enough to eat their fill and then moving on. Ectoparasites that spend their entire lives on their hosts have several attributes that keep them attached to their hosts. Whale lice, which are generally found in skin lesions, nostrils, and eyes of marine mammals, have claws on the tips of their legs that pierce the skin of the whale or dolphin host ([Figure 55.8A](#)). Most whale lice are associated with a single species of whale and spend their entire lives on one individual whale. The lice feed on algae or flaking skin on the whale's body, causing minor skin damage but no significant health risks.

(A) *Cyamus* sp.

(B) *Macaca fuscata*

Figure 55.8 Ectoparasites Hang On (A) Ectoparasites such as these whale lice on the body of a gray whale are flattened and equipped with strong claws for gripping the

body of their host. Each individual whale has its own population of lice. **(B)** Grooming behaviors among primates are believed to have evolved in response to ectoparasites. Japanese macaques form social groups in which this behavior plays a significant role.

Most hosts actively work to rid themselves of their ectoparasites. Grooming behavior—an important component of the social interactions of many primates — may have evolved in response to ectoparasites. The Japanese macaque (*Macaca fuscata*), for example, is prone to infestation by two species of lice, which tend to lay their multitudinous eggs on the outer surfaces of their host's back, arms, and legs. To keep louse populations in check, macaques form and maintain social bonds that ensure the consistent presence of grooming partners ([Figure 55.8B](#)). Some biologists believe that hairlessness in humans is an evolutionary response to ectoparasites.

Predator populations can cycle with their prey populations

The interaction between predators and prey, including parasites and hosts, not only influences the adaptations that species develop but also their population dynamics. Some predator-prey populations are linked and oscillate in response to one another. What controls such patterns of cycling?

Consider the classic example of predator—prey cycling in the Canada lynx (*Lynx canadensis*) and the snowshoe hare (*Lepus americanus*), which makes up a large portion of the lynx diet. Longterm records from Hudson's Bay Company, a Canadian retailer with a long history in the fur-trading business, show that the numbers of lynx and hares trapped over time reflect a regular cycle in the population sizes of each species, with peak abundances occurring every 10 years but falling to low abundances in the intervening years ([Figure 55.9](#)). In addition, the peak in the lynx population lags behind that of the hare population by 2–3 years. Models of predator—prey interactions suggest that this cycling is the result of a tight coupling between prey and predator: as prey increase in abundance, predators do as well, causing prey numbers to decline as a result of increased mortality. When prey decline, so do predators, causing both predator and prey populations to decrease. At some point, the prey population starts to increase again due to the lack of predation, which then allows the predator population, which lags behind, to increase as well. However, in the case of lynx and hare populations, it is likely more complicated. A long-term study by Charles Krebs and colleagues showed that if lynx are absent or food is added for the hares, predator and prey populations continue to cycle, suggesting that the underlying cause of the cycling may be controlled by environmental factors such as large-scale variability in climate.

Figure 55.9 Lynx and Hare Population Cycles Historical trapping data from the Hudson's Bay Company show that numbers of both hares and lynx fluctuate in a 10-year cycle that is offset by 2–3 years.

Q: Does the peak number of hares typically occur before or after the peak number of lynx?

Why is this so?

Predators can have dramatic effects on communities

As you might imagine, given the reduced growth, reproduction, and survival of prey, predators (including parasites) can have dramatic effects not only on populations but also on communities.

One classic experiment, conducted by Robert Paine in the mid-1960s, showed the strong role that sea star predation has on rocky shore communities of the Pacific Northwest of North America. Paine noticed that one species in the community, the mussel *Mytilus californianus*, dominated in certain zones of the intertidal when the density of its sea star predator (*Pisaster ochraceus*) was low. Through the continual removal of *Pisaster* from the rocky shoreline, Paine showed that sessile invertebrate species number declined as the mussel monopolized space in the absence of its predator. After nearly 3 years, the experimental plots had roughly half the number of sessile invertebrate species compared with the natural condition where *Pisaster* was present ([Figure 55.10A](#)). Subsequent experimental removal of sea stars on New Zealand rocky shores, which share no species in common with the Pacific Northwest, resulted in similar reductions in sessile invertebrates ([Figure 55.10B](#)). Paine's research on the sea star—mussel interaction showed not only that predation can affect the number of species in a community but that the effect can be controlled by one or a few species, which Paine called [keystone species](#) (named after the single wedged-shaped stone in the center of an archway called the “keystone” that holds all the other stones in place). Keystone species have large effects, not because of their abundance but because of the important role they play in communities. You'll learn more about keystone species in [Chapter 56](#).

(A) Sea stars of the Pacific Northwest

(B) Sea stars of New Zealand

Figure 55.10 Sea Star Predation on Mussels Has Community– Wide Effects

Along the coasts of the Pacific Northwest of North America and New Zealand, sea stars preferentially feed on mussels, creating bare space for other sessile invertebrates such as acorn and gooseneck barnacles. Experiments by Robert Paine demonstrated that when sea stars were removed from the rocky shore, mussels outcompeted other sessile invertebrates for space, resulting in a decline in the number of invertebrate species in both **(A)** the Pacific Northwest and **(B)** New Zealand.

keystone species Species that have strong community-wide effects despite their small size and abundance.

Some of the most compelling examples of the effects of predation on communities come from human–caused events such as the extinction (or near extinction) of predators, as in the case of wolves living in Yellowstone National Park (see [Key Concept 56.3](#)), or from the introduction of

novel predators into communities. As you saw in the opening of this chapter, the inadvertent introduction of lionfishes to the Atlantic Ocean from the Pacific Ocean has led marine ecologists to hypothesize that there may be drastic effects for reef communities.

55.2 recap

Predation is a fundamental species interaction because all animals must feed. Predator—prey interactions result in the evolution of a range of capture mechanisms (extremes of swift pursuer to inconspicuous ambusher) and avoidance mechanisms (including avoiding detection, chemical defenses, warning signals, mimicry, and behavior). Most parasites specialize on hosts, and most hosts have many species of parasites. Predator populations can cycle with their prey and can have dramatic effects on communities,

learning outcomes

You should be able to:

- Classify prey defenses against predators in terms of type (e.g., behavioral, chemical, morphological).
- Give examples of plant defenses against herbivores and of reciprocal adaptations of herbivores to these defenses.
- Describe variations in parasite—host relationships and infer the causes of these variations.
- Predict future population sizes, given information on current population numbers, in cycling predator—prey populations.

1. Given what you know about lionfish feeding behavior, describe some avoidance mechanisms that might evolve in small reef fish in the Atlantic, to avoid being eaten by lionfishes.
2. What characteristics of herbivory and parasitism are likely important in promoting specialization?
3. Suppose the number of grass species in an alpine meadow is maintained by herbivory by hares. By feeding on the dominant space—occupier, the hares allow less dominant grass species to thrive (similar to the sea star—mussel example in [Figure 55.10](#)). Now suppose lynx predators are introduced into the system. When, in the population cycle of lynx and hare (see [Figure 55.9](#)), would you predict the number of grass species to be highest? When would it be lowest?

Predator—prey interactions are intrinsically compelling; the idea of a lionfish “vacuuming up” tiny reef fishes naturally captures our attention. But at the same time, lionfishes are not the only predators of reef fishes; sharks, barracudas, and even turtles hunt small reef fishes, potentially reducing the food available for lionfishes. Whenever any shared resource is limiting, organisms may compete to varying degrees to get that resource. In the next section we will consider how competition influences the ecology and evolution of species that overlap in their use of a limiting resource.

55.3 Competition Is a Negative Interaction in which Species Overlap in the Use of Some Limiting Resource

Virtually no species has exclusive access to any given set of resources. All species must compete with other species for at least some resources. **Resources** are simply the components of the environment—such as food, water, light, and space — that are required by all species. The full set of these resources, in part, determines the **niche** of a species, defined as the physical and biological conditions required for growth, reproduction, and survival. Thus a species' niche defines where it can and cannot live. Although a species might be physiologically able to live under a wide range of conditions, competitors may restrict its use of those resources. Thus every species has a **fundamental niche**, defined by its physiological capabilities, and a **realized niche**, defined by its interactions with other species.

resource Components of the environment such as food, water, light, and space that are required by all species.

niche (nitch) [L. *nidus*: nest] The set of physical and biological conditions a species requires to grow, reproduce, and survive.

fundamental niche A species' niche as defined by its physiological capabilities. (Contrast with realized niche.)

realized niche A species' niche as defined by its interactions with other species. (Contrast with fundamental niche.)

focus your learning

The fundamental niche determines where a species can physiologically live, but its realized niche depends on interactions with other species, especially competitors,

Interference competition occurs when interacting species actively interfere with each other's access to limiting resources, while exploitation competition occurs when interacting species reduce the quantities of their shared but limited resources,

Most species involved in competitive interactions show coexistence, which is maintained through a variety of ecological processes, including resource partitioning, environmental conditions, disturbance, and predation.

As you saw in [Key Concept 54.1](#), intraspecific competition for resources is the main reason why populations do not grow indefinitely, and instead eventually reach some limit defined by their carrying capacity. *Interspecific* competition—competition among different species—affects individuals in much the same way. At some point an essential resource, or set of resources, may be in such short supply that competition becomes a factor in a population's growth. Such a resource that is in short supply is referred to as a **limiting resource**. At one extreme, if a species can prevent another species from using essential resources, the inferior competitor may become locally extinct, a result called **competitive exclusion**. In reality, though, most species show some sort of **competitive coexistence**, or the ability to coexist with one another despite

sharing limiting resources. Competitive coexistence is maintained through a variety of ecological processes.

limiting resource The required resource whose supply (or lack thereof) most strongly influences the size of a population.

competitive exclusion A result of competition between species for resources, in which one species completely eliminates the other from a given habitat. (Contrast with competitive coexistence.)

competitive coexistence The ability of species to coexist with one another despite sharing limiting resources. (Contrast with competitive exclusion.)

Assuming competitive coexistence occurs, competition can manifest itself either directly or indirectly. **Interference competition** occurs when one species directly interferes with or excludes another species' access to a limiting resource. Interference competition can take many forms, from physical exclusion to chemical warfare among the competitors. A graphic example involves two ant species: the desert ant *Conomyrma bicolor* and the honeypot ant *Myrmecocystus mexicanus*. These species occupy the same habitat type—arid areas containing little vegetation—and they feed on similar foods—the sugary excretions of aphids and other sapfeeding insects. When *C. bicolor* workers find the entrance of a honeypot ant nest, they pick up small stones in their mandibles, carry them to the rim of the nest opening, and drop them down the hole — up to 200 stones in a 5-minute interval. This activity stops the honeypot ants from foraging and temporarily limits competition for food with the desert ant.

interference competition Competition in which one species actively interferes with another species' access to a limiting resource. (Contrast with exploitation competition.)

Exploitation competition occurs when a limiting resource is available to all competitors but the outcome of the interaction depends on the relative efficiency with which each species uses the resource. Exploitation competition affects the availability of a resource for another species but not in an exclusionary way, as we see with interference competition. Exploitation competition may lead to coexistence, provided that the species relying on the same resource have ways to divide up, or partition, that resource. For example, in the American Southwest at least three species of bees consume the nectar of the shin dagger agave (*Agave schottii*). The three bee species differ in where and when they collect shin dagger nectar. Honey bees tend to forage in places with the greatest numbers of shin dagger flowers, bumblebees in places with intermediate numbers of flowers, and carpenter bees where flowers are few and far between. Honey bees also tend to be most active when nectar output is greatest. With their larger nests and greater numbers of offspring to support, honey bees require greater foraging efficiency and greater energy intake. Foraging sites that are not worth their time are left to the other bees.

exploitation competition Competition in which both species reduce the quantities of their shared but limited resources. (Contrast with interference competition.)

The bee—shin dagger agave example is one in which closely related bee species compete for agave nectar. But competition is not limited to closely related species; it commonly occurs among distantly related species as well. Bats and hummingbirds also visit shin dagger agave for its nectar. Even humans harvest agave (albeit the leaves rather than the nectar) to be used as

an alternative for sugar.

Another important aspect of competition is that it is often asymmetrical (unequal): one species can be more negatively affected by the interaction than the other. Clearly this is the case under conditions of competitive exclusion, when one species drives the other to local extinction. But even when species coexist under competition, competitive success forms a continuum, as you saw with red and gray squirrels in the United Kingdom (see [Figure 55.2](#)). The effects of competition can vary for many reasons. Morphological, physiological, or behavioral differences can affect a species' ability to obtain limiting resources. In addition, the magnitude of competitive interactions can vary depending on environmental conditions and how they affect the competitive ability of individual species. We'll discuss how the outcome of competitive interactions can be modified by environmental factors below, but first let's consider the ways in which species can divide limiting resources to reduce their competitive effects on one another.

Resource partitioning allows species to coexist despite overlapping use of limiting resources

Even though the potential for intense competition is high, various ecological and evolutionary mechanisms reduce competition. As you saw with the bee—shin dagger agave example, one way is through [resource partitioning](#), or the sharing of limiting resources by using them in different ways. Another example of resource partitioning comes from the classic experiments performed by G. F. Gause in the 1930s using *Paramecium*, a single-celled protist. Gause grew three species of *Paramecium* in test tubes filled with growth medium that contained bacteria and yeast for food. When grown alone, each species showed [* logistic population growth](#) and reached a stable carrying capacity ([Figure 55.11A–C](#)). When pairs of species were grown together, however, they faced two possible outcomes: extinction or coexistence. *Paramecium caudatum* became extinct in the test tubes in the presence of *P. aurelia* but not when grown with *P. bursaria* ([Figure 55.11 D and E](#)). The difference in outcome, Gause suggested, was a consequence of *P. caudatum* and *P. aurelia* both competing for bacteria as a food source, while *P. bursaria* avoided competition by eating the other food source, yeast. Thus *P. caudatum* and *P. bursaria* partitioned their food resource in the presence of one another and were able to coexist as a result.

resource partitioning A situation in which species share limiting resources by using them in different ways, thereby allowing them to coexist.

Figure 55.11 Competitive Exclusion or Coexistence? G. F. Gause grew three species of *Paramecium* in tubes filled with medium containing bacteria and yeast. **(A–C)** When grown alone, each species reached a stable carrying capacity. **(D, E)** When grown in pairs, *P. caudatum* faced two possible outcomes—extinction or coexistence—depending on whether *P. aurelia* or *P. bursaria* was present. *P. caudatum* and *P. aurelia* both fed mainly on floating bacteria, while *P. bursaria* fed mainly on yeast cells.

Q: Predict what would happen if *P. caudatum* and *P. bursaria* both fed mainly on yeast cells.

In some cases individuals within a species evolve different behaviors or morphologies depending on whether they are competing for resources with other species. Darwin remarked in *On the Origin of Species* that “Natural Selection leads to divergence of character; for more living beings can be supported on the same area the more they diverge in structure, habits, and constitutions.” This “divergence of character” is referred to today as **character displacement**. On some of the islands of the Galápagos archipelago, for example, certain cactus species are pollinated exclusively by the small ground—finch (*Geospiza fuliginosa*), for which cactus nectar is an important food source (see [Figure 22.8](#)). On other islands, a carpenter bee (*Xylocopa darwinii*) competes with the finches for cactus nectar; the birds consequently feed more often on seeds and insects. On the islands where bees are absent, the nectar—feeding birds have smaller wingspans, presumably to make it easier for them to negotiate the flowers.

character displacement An evolutionary phenomenon in which species that compete for the same limiting resources diverge in morphology and/or behavior.

Sometimes organisms respond to competition by moving. The African wild dog (*Lycaon pictus*) (see [Figure 58.17](#)) is a carnivore that lives and forages in packs (groups of related individuals). Frequent vocalizations, called twitters, function to keep the pack together, but these acoustical signals also can alert the dogs’ competitors, African lions (*Panthera leo*), to the presence of prey. Lions hearing the dogs’ twitters can use them to locate dog packs and steal their kills. The dogs avoid competing with lions by selecting areas for their dens where the likelihood of being overheard by lions is low. The wild dog is considered a **fugitive species**—a species that leaves an otherwise suitable habitat in order to avoid competition with another species.

fugitive species A species that leave an otherwise suitable habitat in order to avoid competition with another species.

The physical environment, disturbance, and predation can each alter the outcome of competition

The outcome of competition among species can be changed by a variety of factors, including the influence of the physical environment and processes such as disturbance and predation, which may injure or kill some individuals. These factors can cause a weakening or even a reversal of competitive outcomes between species if they negatively affect the competitively dominant species. By reducing the growth or survival of the competitively superior species, the physical environment, disturbance, or predation can allow the competitively inferior species a chance to acquire limiting resources, gain a foothold, and potentially increase its population size.

In an example from a Rhode Island salt marsh, Mark Bertness and colleague showed how competition could be altered by the effect of daily tides; on the interaction between a rush, *Juncus gerardii*, and a shrub, *Iva frutescens*. Through a series of *Juncus* and *Iva* removal

experiments in each tidal zone, the researchers found that in the relatively physically benign high intertidal, *Iva* is the competitive dominant, shading *Juncus* and causing it to have lower biomass ([Figure 55.12](#)). However in the low intertidal, where salinity and waterlogging from the tides are greater, *Iva* cannot compete with *Juncus* because it is physiologically intolerant of the physical conditions in this zone. In fact, the competitive relationship is turned into a positive one, in which *Iva* is dependent on *Juncus* to survive in the low intertidal. We'll discuss the role of positive interactions in the next section, but it is clear from examples such as this that the outcomes of species interactions depend on the particular circumstances, or context, under which they occur.

Figure 55.12 Species Interactions in a Salt Marsh Plant species removal experiments showed that the shrub *Iva frutescens* competitively dominates the rush *Juncus gerardii* in the high intertidal where physical conditions are benign. But the interaction switches to a positive one in the low intertidal, where the tides flood on a daily basis and *Iva* grows better in the presence of *Juncus*.

Competition can affect species' distributions

Competition can be important in determining where species are found. As you saw earlier, although species may be physiologically able to live under a wide range of conditions, competitors may restrict their use of resources to particular locations. An example of how competition can affect species distributions comes from the rocky intertidal zone of Scotland. Two species of barnacles, the acorn barnacle (*Semibalanus balanoides*) and Poll's stellate

barnacle (*Chthamalus stellatus*), compete for space on the rocky shorelines of the North Atlantic Ocean. The planktonic larvae of both species settle in the intertidal zone and metamorphose into sessile adults. The smaller stellate barnacles generally live at higher levels in the intertidal zone, where they face longer periods of exposure and desiccation (drying out) than do acorn barnacles, which live at lower levels. There is little overlap between the areas occupied by adults of the two species ([Figure 55.13](#)). What explains their distinct distributions in the intertidal zone?

Figure 55.13 Interspecific Competition Can Restrict a Species' Range

Interspecific competition with acorn barnacles (*Semibalanus*) restricts stellate barnacles (*Chthamalus*) to a smaller portion of the intertidal zone than they could otherwise occupy. Larvae of both species settle throughout the intertidal, but at lower levels rock barnacles grow much faster and eliminate the stellate barnacle larvae. In the upper reaches of the intertidal, however, the greater susceptibility of acorn barnacles to desiccation (drying out) allows stellate barnacles to outcompete them. The two species can coexist in a small portion of the intertidal zone.

In a famous study conducted more than 50 years ago, Joseph Connell experimentally removed one or the other species of barnacle from its characteristic zone and observed the response of the remaining species. Stellate barnacle larvae normally settle in large numbers throughout much of the intertidal zone, including the lower levels where acorn barnacles are found (their fundamental niche), but they thrive at those lower levels only when acorn barnacles are not present (their realized niche). Connell found that the acorn barnacles grew so fast they smothered, crushed, or undercut the stellate barnacle juveniles. However, removing stellate barnacles from their spots higher in the intertidal zone did not lead to their replacement by acorn barnacles; the acorn barnacles are less tolerant of desiccation and failed to thrive there even when stellate barnacles were absent. The result of the competitive interaction between the two species is a distinctive pattern of intertidal zonation, with stellate barnacles restricted in their distribution by competition and acorn barnacles restricted in their distribution by their physiological limitations.

55.3 recap

Competition occurs when species overlap in their use of limiting resources, either through interference or exploitation. At one extreme, if a superior competitor prevents another species from using essential resources, the inferior species may be competitively excluded. In reality, most species show competitive coexistence, which is maintained through a variety of ecological processes, including resource partitioning, environmental conditions, disturbance, and predation. The distribution of a species may be affected by competition when another species restricts the use of limiting resources to a particular location.

learning outcomes

You should be able to:

- Contrast the concepts of fundamental niche and realized niche, and distinguish each with examples.
- Distinguish between interference competition and exploitation competition, and give examples of each.
- Describe how both competitive exclusion and competitive coexistence affect interspecific competition and the population growth of interacting species.

-
1. The fundamental niche of the native Eurasian red squirrel includes all of the United Kingdom. Since the introduction of the eastern gray squirrel, a non-native competitor, the Eurasian red squirrel's distribution is restricted to the northern regions of Scotland and Ireland. How has the realized niche of the red squirrel changed in response to the species' interactions with the gray squirrel?
 2. Refer to Question 3 in the [Key Concept 55.2](#) recap. What species interaction controls the coexistence of competing grass species? Explain how this interaction can promote species diversity.
 3. Suppose you are sharing a milkshake with a friend. You each have a straw. Under scenario 1, you both drink from your straws, eventually consuming the entire milkshake together. Under scenario 2, your friend takes both straws and drinks the whole milkshake. Which scenario is an example of interference competition and which is an example of exploitation competition?

Prior to the 1990s, most ecologists believed that positive interactions were interesting, unusual phenomena, but of limited importance to populations and communities. Most of their focus was on the role of negative interactions such as predation and competition. But research over the last few decades shows that just like negative interactions, positive interactions can have important consequences for the growth, reproduction, and survival of species, especially under stressful conditions. Let's turn our attention to how positive interactions might promote the coexistence of species.

***connect the concepts** Logistic population growth occurs when intraspecific competition causes population growth to slow down and eventually level off at some size known as the carrying capacity. Review [Key Concept 54.2](#).

55.4 Positive Interactions Occur When at Least One Species Benefits and None Are Harmed

Positive interactions, or facilitations, are ubiquitous on Earth. Consider the simple fact that most vascular plants have beneficial pollinators, seed dispersers, and root-associated fungi and bacteria that are key to their survival. Consider all the species that provide essential habitat for other species. These positive interactions, while common, were often overlooked or underappreciated until recently.

focus your learning

- Positive interactions, including mutualisms and commensalisms, are ubiquitous on Earth and occur among all types of organisms.
- Conditions in stressful environments can limit species; positive interactions can ameliorate stressful conditions for affected species.
- Positive interactions have important effects on both population growth and community structure.

As mentioned in [Key Concept 55.1](#), there are two types of positive interactions: mutualisms, in which both species benefit from the interaction, and commensalisms, in which one species benefits and the other is unaffected. Some positive interactions are symbiotic. In addition, some interactions can be [obligate](#) (necessary) while others are [facultative](#) (optional).

- obligate** A type of species interaction that is necessary to at least one species involved in the interaction. (Compare with facultative.)

facultative A type of species interaction that is optional to at least one species involved in the interaction. (Compare with obligate.)

[Table 55.1](#) lists mutualistic interactions that range from highly specialized obligate symbioses to highly generalized facultative nonsymbioses. Mutualistic interactions allow organisms to access limiting resources and often involve an exchange of food for housing or defense. Plants and their mycorrhizal fungi (see [Key Concept 29.2](#) and [Figure 29.9](#)), corals and their photosynthetic endosymbionts (see [Key Concept 26.4](#)), and lichens formed from fungi and photosynthetic algae (see [Key Concept 29.2](#) and [Figure 29.9](#)) all provide examples of obligate and/or facultative mutualistic interactions in which food is exchanged for housing and nutrients.

table 55.1 Examples of Mutualistic Interactions				
Interaction	Obligate symbiosis	Facultative symbiosis	Obligate nonsymbiosis	Facultative nonsymbiosis
Plants–mycorrhizal fungi	x	x	x	x
Corals–algal endosymbionts	x	x		

Lichens (algae–fungi)	x		
Plants–insect pollinators		x	x
Plants–animal dispersers		x	x

Some common mutualisms occur between sessile organisms — particularly flowering plants — and mobile animal species that can pollinate flowers or disperse their offspring. These interactions can be highly specialized or very general and facultative. For example, about three—fourths of the 250,000 flowering plant species on Earth require the transport of pollen by an animal partner. The benefit from the plant's perspective is clear: the animals move pollen from one plant to another and thereby promote sexual reproduction and thus genetic diversity. The most direct reward for pollinators is the pollen itself, which serves as food. Plant reproduction would not be served, however, if pollinators were to eat *all* of a plant's pollen; thus plants have evolved various adaptations to ensure that they benefit from the exchange. For example, some plants have two types of anthers: feeding anthers to produce pollen for pollinators, and fertilization anthers to produce pollen for reproduction.

Plants not only need to attract pollinators, but must also ensure that those pollinators carry their pollen to other members of the same species. Repeat visits by a pollinator to different individuals of a particular plant species increase the likelihood that the pollen will end up on the appropriate stigma; thus some plants have adaptations to encourage repeat visits by a given animal, while discouraging others. The nectar of tobacco flowers, for example, contains trace amounts of nicotine, an insecticidal neurotoxin. Many flower visitors, including hummingbirds, can ingest only tiny amounts of nicotine—laced nectar before moving on to other flowers. To other pollinators, however, nicotine may actually be addictive. Putting small amounts of a potentially addictive substance in nectar may be one way tobacco plants improve their odds of a repeat visit by the right pollinator species.

Many animals that eat fruits (called **frugivores**) provide a valuable service to the plants that produce those fruits by dispersing seeds. Seed dispersal by animals not only offers plants the advantages of delivery to potential germination sites away from the parent plant (described in [Key Concept 37.1](#)), but comes with the bonus of organic fertilizer for the seeds. Interactions between plants and frugivores, however, are not always reciprocal; in many cases, one party benefits more than the other. Whereas the frugivore is paid “in advance” for its transportation services, the seeds may never reach an appropriate destination for germination (your windshield, for example, will not do). From the plant's perspective, its partnership with frugivores requires a delicate balance between discouraging them from eating fruits before the seeds are capable of germinating and attracting them when the seeds are ready. In addition, the plant must protect the seeds from destruction in the frugivore's digestive tract and defend them against inappropriate consumers that would damage the seeds or fail to disperse them at all.

frugivore [L. *frugis*: fruit + *vorare*: to devour] An animal that eats fruit.

Positive interactions are more common in stressful environments

It is clear from the previous examples that positive interactions arise out of net positive benefits accrued by one or more species involved in the interaction. Over the last two decades studies have repeatedly shown that positive interactions, be they mutualisms or commensalisms, are more likely to occur in stressful environments such as deserts, salt marshes, and alpine communities. In these environments, where physical conditions can limit fitness, some species provide benefits for those species that lack mechanisms to deal with the stressful conditions.

A comprehensive study conducted by Ray Callaway and an international group of ecologists testing for the influence of positive interactions in alpine plant communities around the world illustrates the benefits of these interactions in stressful environments ([Figure 55.14](#)). The

experiment was conducted on 11 mountain ranges and involved either removing neighboring plants around target plants or keeping them in place as controls (in total, 115 plant species were used). The experiment was conducted at both high—mountain elevations where temperatures are lower and at low—mountain elevations where temperatures are higher. A year later, the relative effect of the neighbor on the growth of the target plants was measured. Researchers found that target plants benefitted from their plant neighbors at high elevations simply as a consequence of the thermal protection that living close together provides under cold temperatures. In contrast, target plants competed with neighboring plants at low elevations, where temperatures are moderate and the same dense plant growth resulted in competition. Whether the observed positive interactions were mutualisms or commensalisms is unknown because the effects of the target species on the neighboring plant species were not measured. Nonetheless, in this and other studies (e.g., see [Figure 55.12](#)) it is clear that positive interactions can arise under a variety of stressful conditions.

Figure 55.14 Positive Plant Interactions Are More Common at Higher Elevations

The species interactions of alpine plants were experimentally measured (using the relative neighbor effect [RNE], defined as the growth of the target plant species with neighboring plants present minus its growth with neighboring plants removed) in 11 mountain ranges worldwide. RNE values greater than zero (in blue) indicate that neighbors increased the growth of target species; RNE values less than zero (in red) indicate that neighbors decreased the growth of target species. Plants generally benefited from neighbors at high elevations where temperatures were colder and competed with them at lower elevations where temperatures were warmer.

Positive interactions can have dramatic effects on populations and communities

You have seen how positive interactions influence the physiology, behavior, and growth of

species. Research has shown that positive interactions have effects at the population and community levels as well.

As you know from population biology, any interaction that affects the survival of individuals in a population can affect population growth. One example of the effects of a mutualism on population growth comes from an interaction between ants and acacia trees in Central America. In 1874, in Nicaragua, the naturalist Thomas Belt observed a peculiar interaction between bullhorn acacia trees (*Acacia cornigera*) and *Pseudomyrmex* ants. Bullhorn acacias get their common name from the enlarged, hollow thorns, in which the ants build nests. The trees also produce rewards for the ants, both in nectar—producing extrafloral structures and modified leaflet tips that are rich in oil and protein. These structures have no apparent purpose other than providing food for ants.

Belt suggested that the notoriously aggressive acacia ants defend the plants against herbivores in exchange for food and shelter. This idea was tested by Daniel Janzen in 1966 when he removed ants from some acacias with insecticide, and showed that trees without ants suffered a reduction in growth and an increase in mortality (**Figure 55.15**). If a bullhorn acacia tree lacks an ant colony, the repeated loss of its leaves and growing tips to herbivores often kills the plant within 6–12 months. Since Janzen conducted his experiment, additional work on ants and acacias has revealed that ants do more than simply defend the plant against herbivorous enemies; they also clip weeds from around the base of the plants, presumably reducing competition. Thus the ant–acacia mutualism has considerable effects on the population size of each partner.

Animation 55.1 Mutualism www.Life11e.com/a55.1

Finally, possibly one of the most important types of positive interactions is that of species that provide habitat for other species and thus have widespread community effects. These dominant species mostly include plants such as trees or kelps but can include animals such as corals and sponges. For example, coral reefs are home to many species of fish that cannot survive outside the reef environment. Likewise, species that are forest specialists cannot survive outside the cool and shaded environment of trees. Most tree species facilitate many other types of species by simply providing sites for attachment, shelter from extreme environmental conditions, or

hiding places from predators. Many of these species have no direct effect on the trees in which they live, and thus have a commensalism with the trees. In all these cases, these dominant plants and animals are the very foundation of the community, which would not exist without them.

55.4 recap

Positive interactions, when at least one species benefits from an interaction and none are harmed, play a key role in enhancing coexistence among species. Positive interactions are more common in stressful environments, where physical conditions can limit the population growth of some species. Positive interactions can have dramatic effects on populations and communities, especially by providing habitat for other species.

focus your learning

You should be able to:

- Give reasons why the types of mutualistic interactions, from generalized to specialized, and from obligate to facultative have evolved.
 - Explain, with examples, why stressful environments are more likely to give rise to positive species interactions.
 - List examples in which one species serves as habitat for other species. Explain whether each situation represents mutualism or commensalism, and justify your answer in each case.
-
1. Offer reasons for why insect pollinators and animal dispersers might evolve obligate versus facultative mutualistic relationships with plants.
 2. Refer to [Figure 55.13](#), Where in the rocky intertidal might *Semi— balanus* benefit from positive interactions with other species? How about *Chthamalus*? Explain your answer.
 3. Give an example of how species that provide habitat could affect the number of species in a community.

investigatinglife

Why are small coral–reef fish species so vulnerable to lionfish predation, and what can be done about it?

You have seen that this question is greatly informed by understanding the power that species interactions have on shaping the behavior, physiology, and morphology of interacting species. It is clear that the longer species are exposed to one another, the more likely it is that they will develop strategies that allow coexistence. When lionfishes were inadvertently introduced to coral reefs in the Atlantic Ocean, native coral–reef fishes were exposed to a simple but novel predator behavior for which they currently have no viable defense mechanisms. It is unclear whether native coral–reef fishes will evolve defensive mechanisms before coral–reef fish communities are irreparably damaged. One potential strategy to slow the invasion may be to introduce predators of lionfishes. Unfortunately, however, lionfishes are well defended by frilly fin rays with venomous spines and a zebra-like barred

coloration that provides crypsis. To make matters worse, populations of predators that might control lionfish populations (such as sharks) are drastically declining as a consequence of overfishing. Fortunately lionfishes are relatively easy to catch, and the future may lie in controlling the population through systematic harvesting by humans.

Future directions

Some people have argued that the best way to control lionfishes is through commercial fishing. Lionfishes are attracted to lobster traps and can also be easily speared. The only risk to harvesters is in being poked by the spines, but this can be avoided if the fish are handled with care. After some initial skepticism, restaurant owners are realizing that lionfish are very good eating; the meat has a light, buttery flavor. Efforts are now ramping up to create a market for this destructive invader. Lionfish and chips, anyone?

► 55.1 Species Interactions Vary in Direction and Strength across a Continuum

- Species vary in the effects they have on each other (positive, negative, neutral). Species interactions may involve feeding (**trophic**) effects and/or living in close association (**symbiosis**).
- The four main categories of species interactions are **predation** (predator kills and/or consumes its prey, or part of its prey), **competition** (at least two species use some of the same limiting resources and have negative effects on one another), **positive interactions**, or **facilitations** (at least one species benefits from the interaction and none are harmed), and **amensalism** (one species is harmed but the other is not affected).
Review Focus: Key Figure 55.1, Activity 55.1
- Species interactions are not always clear-cut but instead fall along a continuum in which species vary in how strongly they affect one other. **Review Figures 55.2, 55.3**
- Some species interactions result in reciprocal evolutionary change over time, also known as coevolution. **Review Activity 55.2**

► 55.2 Predation Is a Trophic Interaction in which Predators Benefit and Prey Are Harmed

- Predator—prey interactions result in the evolution of a range of capture and avoidance mechanisms. **Review Figures 55.4, 55.5, 55.6, Activity 55.3**
- **Herbivory** (animals preying on plants) and **parasitism** (parasites feeding and living on or in hosts) are widespread but specialized interactions that usually do not result in the death of the prey. **Review Figures 55.7, 55.8**
- Population sizes of predators and their prey tend to cycle as a result of predator—prey interactions over time. **Review Figure 55.9**
- Some predators, called **keystone species**, can have dramatic effects on communities by preying on competitively dominant species. **Review Figure 55.10**

► 55.3 Competition Is a Negative Interaction in which Species Overlap in the Use of Some Limiting Resource

- **Interference competition** occurs when one species directly interferes with or prevents another species' access to a limiting resource. **Exploitation competition** occurs when all competitors have access to the limiting resource but the outcome depends on their relative efficiency at using the resource.
- **Competitive exclusion** occurs when a species prevents another species from using essential resources, which may cause the inferior competitor to become locally extinct.
Review Figure 55.11 D
- Most competing species show **competitive coexistence** through the processes of **resource partitioning**, disturbance, stress, and/or predation. **Review Figures 55.11E, 55.12, 55.13**

► 55.4 Positive Interactions Occur When at Least One Species Benefits and

None Are Harmed

- The two types of positive interactions are **mutualisms**, in which both species benefit from the interaction, and **commensalisms**, in which one species benefits and the other is unaffected. Some positive interactions are symbiotic relationships. Some positive interactions are **obligate** (necessary), while others are **facultative** (optional). **Review** [Table 55.1](#) , [Animation 55.1](#)
- Positive interactions are more common in stressful environments, where physical conditions can limit the abundance and distribution of some species. **Review** [Figure 55.14](#)
- Positive interactions can have dramatic effects on populations and communities, especially by providing habitat for other species.

Go to **LearningCurve** (in **LaunchPad**) for dynamic quizzing that helps you solidify your understanding of this chapter. **LearningCurve** adapts to your responses, giving you the practice you need to master each key concept.

► Apply What You've Learned

Review

- 5.1 Broad categories of species interactions are predation, competition, positive interactions, and amensalism.
- 5.1 Species interactions are often dynamic and asymmetrical; that is, species have unequal effects on one another.

Original Paper: Bartomeus, I., J. S. Ascher, D. Wagner, B. N. Danforth, S. Colla, S. Kornbluth et al. 2011. Climate-associated phenological advances in bee pollinators and bee-pollinated plants. *Proceedings of the National Academy of Sciences USA* 108: 20645—20649.

Rising global temperatures due to climate change affect the timing of natural events, including insect pollination and other species interactions. As temperatures rise, these events happen earlier. Not all species react to these changes in similar ways, and this can result in timing mismatches. For example, if the timing of insect emergence varies too much from that of flowering, pollination may not occur.

Scientists looked at 3,447 museum specimens of native bee species dating back to the 1870s. They chose 10 bee species that are known to range across North America, emerge in early spring, and pollinate both crops and wild plants. The scientists then compared the predicted pollination date for individual bees with flowering times of bee-pollinated spring plants measured in other studies. Dates of bee pollination activity and flowering times were correlated with temperature data in the same geographic areas.

Figure A shows scatter plots of the distribution of predicted pollination dates for individual bees between 1870 and 2010 (top) and the mean April air temperature between 1900 and 2010 (bottom). Predicted pollination date is the number of days between January 1 and the bee-collection date, a time in which bees were assumed to be engaging in pollination activity. Black lines indicate the trends for the entire time period, and red lines show the trends between 1970 and 2010. Statistical analysis revealed a strong positive correlation between predicted pollination dates and mean April air temperature. Between 1880 and 2010, bees advanced their pollination activity by 10.4 days; most of the advance (7.2 days, or 69 percent) has occurred since 1970.

Figure B shows comparisons of the change in days for bee pollination time and plant flowering time for two time intervals. The change in slope between the two dates (bees at left, plants at right) indicates the degree of difference between bee pollination time and plant flowering time for both time intervals. The interval indicates a mismatch of 4—6 days over the 118-year span of the longer study (1885—2003). For the more recent study (1971—1999), when mean April air temperature changed the most, the mismatch was 5 days over just 30 years.

Figure A

Figure B

Questions

1. Characterize the type of interaction occurring between plants and bees, and explain why it is necessary for the timing of bee emergence and plant flowering to be closely correlated.
2. Explain and analyze the trends shown in the two plots of Figure A. What has happened over time to the trend in bee pollination date and the trend in mean April air temperature? Why are these two trends moving in opposite directions? What is the significance of the difference in slope of the entire time period versus the shorter time period after 1970?
3. Describe differences in the trends shown in the two studies in Figure B, and indicate which study best

supports the hypothesis that climate warming is affecting plant—pollinator interactions.

1. The bees in these studies are generalist species; that is, they feed on (and pollinate) many species of plants, as compared with specialists, which associate with one or a few closely related species. Do you think specialist plant—pollinator interactions would be more or less affected by increasing temperatures? Explain your answer.
2. This is one of few studies conducted to date on the effect of climate change on plant—pollinator species interactions. How would you design a multiyear study to give more specific information about the presence (or absence) of timing mismatches between the emergence of insect pollinators and spring flowering of plants?

investigatinglife

Rising from the Ashes

When Mount St. Helens in Washington State erupted at 8:30 a.m. on May 18, 1980, almost all living things for miles around were obliterated in an instant. A huge magma-filled bulge that had been forming for months exploded, creating the largest avalanche in recorded history. Mud and rock flowed down Mount St. Helens and were deposited on alpine meadows, lush forests, and crystal-clear lakes and ponds, tens of meters deep in some areas. The bulk of the avalanche traveled to the North Fork Toutle River, where it scoured the entire valley, from floor to rim, with volcanic material. A huge pile of vegetation was deposited downstream. The blast also produced a cloud of hot air that burned forests to ash near the mountain, blew down trees over a large area, and left dead but standing trees for miles.

Volcanic eruptions are so rare that studying the after-effects of the Mount St. Helens eruption gave ecologists an unprecedented view into how ecological communities respond to extreme natural catastrophes and the recovery processes they undergo. The event created brand-new environmental conditions to which colonizing species had to respond. At one extreme was the Pumice Plain, a large, gently sloping area close to the lava dome that had once been covered in alpine meadows and forests. Pelted with hot, sterilizing pumice (a light and porous volcanic rock), it was now a harsh moonscape-like environment that lacked life and organic matter of any form. In the aptly named Blowdown Zone, covering most of the mountain's slopes, the destruction was less catastrophic. Here there was hope of a biological legacy buried beneath the piles of downed trees and vegetation covered in mud and ash. Beyond the Blowdown Zone, forests were covered in debris and ash that spewed from the mountain for months.

Shortly after the eruption, helicopters delivered the first scientists to the mountain. A few fortunate ecologists collected baseline data on the sequence of biological changes that began soon after the eruption. Now, more than 35 years later, hundreds of ecologists have studied the reemergence of life on Mount St. Helens. Much of what has been learned has been unexpected and has changed the way we view the resiliency and recovery of communities after catastrophic events.

QA How have ecological communities on Mount St. Helens responded to the eruption, and what processes have been important to their recovery?

56.1 Communities Are Groups of Interacting Species Occurring Together in Space and Time

In ecological terms, a **community** is a group of species living together at the same place and time. Interactions among multiple species and their physical environment give communities their character and function. Although each species has unique interactions with the other species in its community (as you saw in the previous chapter), ecologists often find it useful to study the properties of the community as a whole.

community A group of species living together at the same place and time.

focus your learning

Ecologists may define communities based on taxonomy, resource usage (guilds), or functional groups.

Ecologists may define communities in terms of food webs or interaction webs.

Species diversity can be measured quantitatively.

The definition of a community given above is more theoretical than practical, in part because communities vary greatly in size and scope. For example, communities can be small and contained, such as that living within the purple pitcher plant (*Sarracenia purpurea*), a species common in North American wetlands ([Figure 56.1A](#)). Pitcher plants collect rainwater and are home to a thriving community of bacteria, protists, rotifers, and mosquito larvae. A community can also encompass a large geographic area, such as a desert ([Figure 56.1B](#)), where the borders of the community are not always well delineated. When borders become unclear, ecologists may designate boundaries somewhat arbitrarily, based on their ability to study the community.

(A)

(B)

Figure 56.1 Defining Communities Communities exist at a variety of spatial scales. The community within a single pitcher plant contains microorganisms and tiny invertebrates **(A)**, whereas a desert community might contain plants and animals over a large, hard-to-delineate, geographic area **(B)**.

Another practical problem in defining communities is determining the number of species present. Most communities contain thousands if not hundreds of thousands of species, from microscopic bacteria to towering trees. Some species are easily identified, but many others are not. Additionally, some species are present only at certain times of the year, for certain life stages, or tend to move among communities. Creating a species list for a community is a huge undertaking—one that is essentially impossible to complete, especially if all small or relatively unknown species are considered. Taxonomists have officially described about 1.8 million species on Earth, but we know from sampling studies of tropical insects and microorganisms that this number greatly underestimates the actual number, which could be 15 million or even more. For this reason, and because of the difficulty of studying many species at one time, ecologists often restrict their definition and study of communities to a particular subset of species.

Ecologists often use a subset of species to define communities

A community can be subdivided on the basis of taxonomic affinity—that is, by groups of organisms classified together because of evolutionary lineage ([Figure 56.2A](#)). For example, all the amphibians in a set of ponds on Mount St. Helens could be considered to be part of an amphibian community. A community can also be subdivided by resource usage. A **guild** is a group of species, often taxonomically distinct, that use similar resources ([Figure 56.2B](#)). For example, bats, birds, and bees all feed on pollen, forming a pollen-feeding guild. Yet another way to subdivide a community is by **functional group**—species that function in similar ways but may or may not use similar resources ([Figure 56.2C](#)). For example, nitrogen-fixing plants (legumes) can be placed in the same functional group.

Figure 56.2 Subsets of Species in Communities Ecologists often use subsets of species to define communities. **(A)** All the amphibian species in a community could be grouped together by taxonomic affinity. **(B)** All the species that use pollen as a resource form a guild. **(C)** All the legumes (e.g., vetch, clover, and peas) that have nitrogen-fixing bacteria could be placed in the same functional group. Species within functional groups may or may not use the same resources.

guild A group of species, often taxonomically distinct, that use the same resources. (Compare with functional group.)

functional group (1) A characteristic combination of atoms that contributes specific properties (such as charge or polarity) when attached to larger molecules (e.g., carboxyl group, amino group). (2) A group of species that function in similar ways, whether or not they use the same resources. (Compare with guild.)

Ecologists also organize communities into a **food web**, a representation of the trophic or energetic connections among species, as illustrated in **Figure 56.3** for Yellowstone National Park. Most communities contain so many species interacting in so many different ways that it is impossible to enumerate (or even identify) all of the links in a food web. Nevertheless, simplified food webs are useful in envisioning the kinds of interactions and sequence of energy flow occurring in a community. Food webs are generally divided by **trophic levels**, with each level including species that have similar ways of interacting and obtaining energy. Primary producers start the chain of trophic levels. At the next level are **primary consumers**—the herbivores that feed on primary producers. Organisms that eat herbivores, called **secondary consumers**, are the next trophic level. Those that eat secondary consumers are tertiary consumers, and so on. Some species, known as **omnivores**, feed on multiple trophic levels. For example, a bird might eat both insects and seeds. Finally, the waste products and dead bodies of organisms (known as **detritus**) provide another source of energy. Organisms that consume such materials are called **detritivores** or **decomposers** and serve an important function by returning nutrients back to the community through the uptake of primary producers. **Scavengers** eat larger dead organisms and are typically not considered detritivores.

food web A representation of the trophic or energetic connections among species within a community.

trophic level A subdivision of a food web that includes species that have similar ways of interacting and obtaining energy.

primary consumer An organism (herbivore) that feeds on primary producers.

secondary consumer An organism (carnivore) that feeds on herbivores or primary

consumers. (Contrast with primary consumer.)

omnivore [L. *omnis*: everything + *vorare*: to devour] An organism that feeds on multiple trophic levels; also an organism that feeds on animals and primary producers. (Contrast with carnivore, detritivore, herbivore.)

detritivore (di try' ti vor) [L. *detritus*: worn away + *vorare*: to devour] An organism that obtains its energy from the dead bodies or waste products (**detritus**) of other organisms, releasing nutrients and energy. (Contrast with carnivore, herbivore, omnivore.)

decomposer See detritivore.

scavenger An animal that eats larger dead organisms but is not typically considered a detritivore.

Figure 56.3 Food Webs Show Trophic Interactions in a Community This simplified food web for the meadows and forests of Yellowstone National Park includes only some vertebrates and the plants on which they depend. The arrows show trophic interactions and energetic connections. Herbivores whose sole source of food is plants (green arrows) are primary consumers. Carnivores that kill and eat animals (purple arrows) are secondary and tertiary consumers. Omnivores such as grizzly bears, coyotes, and ravens eat both plant and animal tissues; ravens and grizzlies also eat carrion (dashed purple arrows), so these species are also scavengers.

Food web depictions can sometimes include nontrophic interactions such as competition and positive interactions (mutualisms and commensalisms). These so-called [interaction webs](#) provide a more realistic view of all the species interactions that might be important in the community. Overall, the food web concept, regardless of whether it includes nontrophic interactions, is a useful visual representation of the important consumer relationships in a community. You will learn more about food webs later in this chapter and in [Chapter 57](#).

interaction webs A concept that describes both the trophic (vertical) and non-trophic (horizontal; such as competition, mutualism, commensalism) interactions among the species in a food web.

Species diversity and composition are important descriptors of community structure

Communities vary widely in species number and [species composition](#) (or the kinds of species) present. A coral-reef community in the Great Barrier Reef, for example, has many more species of fish than one in the Caribbean. As you saw in [Chapter 53](#), ecologists have devoted considerable effort to measuring the variation in species diversity and species composition at multiple spatial and temporal scales (see [Figure 53.12](#)). Patterns at the community or local scale are important descriptors of what ecologists call [community structure](#). Documenting community structure is an important first step in generating hypotheses about how communities work. Let's first consider the different ways that one metric of community structure—species diversity—is measured.

species composition The kinds of species present in a community.

community structure The set of characteristics or patterns that describe a community, including the number, composition, and abundance of species.

Activity 56.1 The Major Trophic Levels www.Life11e.com/ac56.1

We have thus far used the term “species diversity” to describe the number of species in a sample, community, or region, but ecologists have a more technical definition. [Species diversity](#) is a measure that combines the number of species ([species richness](#)) and their relative abundances compared with that of other species ([species evenness](#)).

species diversity A measure that combines the number of species (species richness) in a community and their relative abundances compared with one another (species evenness).

species richness The total number of species within an area.

species evenness The relative abundances of species compared to one another.

The contribution of both species richness and evenness to species diversity is illustrated in the following example from Mount St. Helens ([Figure 56.4](#)). Imagine that we collect samples of 20 individual amphibians in each of two different ponds on Mount St. Helens 3 years after its eruption. Our sample from Pond A contains 17 individuals of one species (Pacific tree frog) and only 1 individual of each of the other three species (an uneven distribution). Our sample from Pond B, however, contains 5 individuals of each of four amphibian species (an even distribution of individuals). Even though the species richness of the two communities is the same (four species), Pond A is less diverse because the less abundant species are encountered less frequently compared with the single most abundant species.

Figure 56.4 Species Richness and Evenness These two hypothetical amphibian pond communities have the same number of species (species richness) but different relative abundance of those species (species evenness).

Q: Which pond, A or B, has higher species diversity as measured using the Shannon index (see [Table 56.1](#))? Explain.

Activity 56.2 Measures of Species Diversity www.Life11e.com/ac56.2

There are several ways to measure species diversity quantitatively. One common measure is the [Shannon index](#),

Shannon index The quantitative index most commonly used to describe species diversity that includes measures of both species richness and species evenness.

$$H = - \sum_{i=1}^s p_i \ln(p_i)$$

$H = - \sum_{i=1}^s p_i \ln(p_i)$

where

H = the Shannon index value

p_i = the proportion of individuals found in the i th species

ln = the natural logarithm
s = the number of species in the community

The lowest possible value of *H* is zero; higher values represent greater species diversity. [Table 56.1](#) calculates the Shannon index for amphibians in the two Mount St. Helens pond communities shown in [Figure 56.4](#). These calculations show that Pond A has the lower Shannon index value (*H*), confirming mathematically that this community has lower species diversity than Pond B. Given that both communities have the same species richness, the difference in species diversity is driven by the lower species evenness in Pond A.

How does the term “biodiversity” relate to species diversity? **Biodiversity** is used in reference to various levels of diversity, from genes to species to communities ([Figure 56.5](#)). Implicit in this term is the interconnectedness of different scales of diversity. For example, you saw in [Chapter 20](#) that greater genetic diversity can lead to greater fitness of populations, which in turn can promote species diversity. The greater number of different types of communities can also lead to greater diversity at larger regional and continental scales, as you saw in [Chapter 53](#).

biodiversity The diversity of important ecological entities that span multiple spatial scales, from genes to populations to species to communities.

Genetic diversity within populations may affect the viability of species...

...which affects species diversity within a community...

...which influences the diversity of communities at larger scales.

Figure 56.5 Biodiversity Considers Multiple Spatial Scales Diversity can be measured at spatial scales that range from genes to species to communities. The term “biodiversity” encompasses diversity at all of these scales.

56.1 recap

A community is a group of species that occur together at the same place and time. Communities are often defined by a subset of species based on similar taxonomy, resource use (guild), ecological functions (functional group), or trophic and energetic connections (food webs). Species diversity and composition are descriptors of community structure. Species diversity is a measure that combines the number of species (species richness) and their relative abundances (species evenness). Biodiversity is a term that describes multiple scales of diversity, from genes to species to communities.

learning outcomes

You should be able to:

- Give examples of ways communities can be subdivided, and explain how these might also be used to understand communities.
- Define food web, and analyze types of information it might provide about community structure.
- Use the equation for the Shannon index to determine the species diversity of a community, given appropriate data.
- Explain the significance of the value of H in the Shannon index.

-
1. Why are subsets of species used to define communities? What type of community subset was used to define the frogs and toads in ponds on Mount St. Helens?
 2. What types of species interactions are missing from the food web depicted in [Figure 56.3](#)?
 3. Refer to [Table 56.1](#). Replace the abundance of amphibians in Pond A with the following values (Pacific tree frog = 6, western toad = 8, northern red-legged frog = 4, Cascades frog = 2), recalculate the values in the other three columns in the table accordingly, and then calculate a new Shannon index value. Which pond has the higher species diversity, Pond A or Pond B?

Measuring community structure prompts us to consider many interesting questions about communities. Why do communities differ in the number and composition of species? What processes determine community membership? In the next section we will explore how community membership is shaped by which individuals get to the community, deal with the environmental conditions there, and form interactions with other individuals.

56.2 Community Membership Depends on Species Supply, Environmental Conditions, and Species Interactions

Suppose you are looking across the landscape of Mount St. Helens. You see lakes and ponds, alpine meadows, and forests. There is no doubt that these communities vary not only in their species composition but also their species richness. The lakes might be dominated by fishes, amphibians, and freshwater algae; the alpine meadows by various species of grasses, flowering plants, and rodents; and the forests by trees, shrubs, and birds. Even though some species might move from one community to another, the three communities would still be very different. How is it that species come together to form different communities?

focus your learning

To become community members, species must be present in a region and able to colonize the community.

Environmental conditions serve as an abiotic filter to determine which species colonize a community.

Species already living in a community serve as a biotic filter, determining which colonizing species succeed or fail.

Community membership depends on three basic factors: (1) the regional species pool and dispersal ability (species supply), (2) physical and chemical environmental conditions (abiotic conditions), and (3) species interactions (biotic conditions). Each factor acts as a “filter” that excludes or includes species in particular communities (**Focus: Key Figure 56.6**). Let’s consider each of these filters in more detail.

focus: key figure

Regional
species
pool

Species that disperse to the community from the regional species pool pass through the species supply filter.

Dispersal

Species that can tolerate or require certain environmental conditions in the community pass through the abiotic filter.

Environmental
conditions

Species restricted by or dependent on particular species interactions in the community pass through the biotic filter.

Species
interactions

Local
community

Figure 56.6 Filters Determine Community Membership Species members are included or excluded in a local community by passing through a set of “filters.” Species are lost at each filter, so local communities contain a fraction of the species in the regional pool. In practice, all the filters work at the same time, rather than in series as the figure suggests.

Q: Would it make sense for the fish and frog species in the regional species pool to be present in the local community shown in the figure? Explain.

Community membership depends on species supply

In [Chapter 53](#) we established that regional species pools provide the upper limits on the numbers and types of species that can live within communities (see [Figure 53.12](#)). An obvious first step to community membership is the presence of species at the regional level, and their ability to disperse to the community. For example, as communities started to recover from the Mount St. Helens eruption, they began to gain species supplied from the regional species pool of the Pacific Northwest of North America. Because they were able to disperse to the mountain, these species began to colonize the new and unique environments created in the aftermath of the devastation.

Maybe the best examples of how species supply affects community membership are seen in the introduction of novel species to communities. Humans have greatly expanded regional species pools, allowing new and potentially invasive species to enter communities. [Chapter 55](#) described the catastrophic effects of the unintentional release of invasive lionfish in Atlantic Ocean and Caribbean coral-reef communities. The lionfish invasion demonstrates that “getting there” is a critical first step to community membership. All it took was the release of this predator, and its extraordinary ability to prey on reef fish, to dramatically change coral-reef communities.

Environmental conditions are critical to community membership

As you might expect, all species in a regional species pool do not end up becoming members of every community in that region. A species may make it to a community but fail to become a member because of unsuitable environmental conditions there. You might think of the influence of the environment as an “abiotic filter” that restricts species that are physiologically incapable of surviving in a given community. The lakes in the Mount St. Helens area, for example, have environmental attributes that accommodate fish, amphibians, and aquatic insects but not trees.

The physical environment can be a significant barrier to introduced non-native species. Consider, for example, marine organisms that are often introduced into foreign ports via ballast water (seawater that is pumped into and out of ballast tanks to stabilize large cargo-carrying ships). Ballast water picked up outside one port and then dumped in another can potentially release organisms (from bacteria to planktonic larvae to fish) that can colonize nearshore communities. While most ballast-water organisms do not survive the thermal, salinity, or light regimes of their new environment, a small percentage are not physiologically constrained by such conditions and may gain a foothold, especially if they are introduced multiple times.

Community membership can shift with changing environmental conditions. For example, growing evidence indicates that climate change—in particular, rising temperatures—may improve conditions for some non-native species, increasing their ability to thrive. Jay Stachowicz and his colleagues found that the recruitment and growth of invasive marine invertebrates known as ascidians (sea squirts) in New England were dependent on warm winter and summer water temperatures ([Figure 56.7A](#)). Warmer temperatures gave the non-native organisms an earlier start in spring and increased the magnitude of their growth relative to that of native sea squirts. A similar story can be told for the European green crab (*Carcinus maenas*), whose

recruitment to estuarine communities along the Pacific Northwest coast is dependent on warm water temperatures during El Niño conditions ([Figure 56.7B](#)).

(A) *Botryllus schlosseri*

(B) *Carcinus maenas*

Figure 56.7 Species Invasions Can Depend on Environmental Conditions (A)

Invasive sea squirts in New England depend on warmer water temperatures to grow and outcompete native sea squirts. **(B)** The recruitment of European green crabs to Pacific Northwest estuaries depends on warm water conditions such as those during El Niño.

The final requirement for species membership is the ability to coexist with other species. Let's consider the mediating effects of species interactions on the inclusion (or exclusion) of species in communities.

Resident species can restrict or promote community membership

Even if a species makes it to a community and is able to tolerate its environmental conditions, it must be able to live with all the other species in that community. It must be able to obtain food, survive without being eaten, and cope with competitors. Thus whether a species is successful in a new community will depend on the presence of resident species that either promote or restrict species membership.

The ability of resident species to exclude or slow the population growth of non-native species is called [biotic resistance](#). While there are a handful of studies showing that competitors and herbivores can slow down the spread of non-native plant species, confirmed examples of biotic resistance are few. Identifying whether biotic resistance is common in nature may reflect the fact that many failed introductions of non-native species go undetected. Nevertheless, the evidence from the invasive species literature suggests that the influence of resident species may be a fairly porous filter when it comes to restricting species from, or promoting species to, communities.

biotic resistance The ability of resident species to exclude or slow the population growth of non-native species.

56.2 recap

Community membership is a consequence of regional species pools, environmental conditions, and species interactions. These three factors act as ‘filters’ that control community membership. Biotic resistance—the process by which species interactions exclude or slow the population growth of colonizing species—is rarely documented.

learning outcomes

You should be able to:

- Name the three factors that determine community membership, and evaluate their relative importance in given situations.
- Explain and illustrate with examples how environmental factors can act as a filter or barrier affecting community structure.
- Explain why studying introduced non-native species provides a unique test of community membership.

1. Refer to [Figure 56.6](#). Which factor is most limiting to the species membership of the local community? Explain.
2. If you were trying to reduce the number of non-native species colonizing Mount St. Helens, what one best general management action would you employ?

Once a species is part of a community, how is it able to coexist with other species there? In the next section we will consider theories and examples that seek to explain how species interactions help form communities of varying composition and diversity.

56.3 Communities Are Complex Networks of Species Interactions That Vary in Strength and Direction

So far we have presented a rather static view of communities as groups of species residing in the same place at the same time. But communities are actually complex networks of species with connections that vary in their strength (i.e., magnitude) and direction (i.e., positive, negative, or neutral). Every species in a community experiences multiple direct and indirect interactions.

focus your learning

Indirect interactions involving three or more species can affect species diversity and abundance in communities.

Keystone, foundation, and ecosystem engineering species have major effects on community structure.

The role of chance in maintaining community structure is poorly understood, but lottery, or neutral, models may help explain it.

Indirect interactions are important to community structure

A **direct interaction** is one that occurs between just two species. **Indirect interactions** occur when the direct relationships between two species are mediated by a third (or more) species (**Figure 56.8**). The addition of a third species to a two-species interaction has the possibility of dramatically changing the outcome of the original interaction.

direct interaction An interaction that occurs between two species, such as predation, competition, or a positive interaction. (Compare with indirect interaction.)

indirect interaction An interaction in which the relationship between two species is mediated by a third (or more) species. (Compare with direct interaction.)

Figure 56.8 Direct and Indirect Species Interactions (A) A direct interaction occurs between two species. **(B)** An indirect interaction (dashed arrow) occurs when the direct relationship between two species is mediated by a third species.

Indirect interactions were observed by Charles Darwin in *On the Origin of Species* (1859). Having described the role of bees in flower pollination and seed production of plants in the region of England where he lived, Darwin hypothesized that the number of bees in the region was dependent on the number of field mice that prey on their combs and nests. Noting that mice, in turn, are eaten by cats, Darwin wrote, “Hence it is quite credible that the presence of a feline animal in large numbers in a district might determine, through the intervention first of mice and then of bees, the frequency of certain flowers in that district!”

Today the term “trophic cascade” would be applied to Darwin’s observations. A [trophic cascade](#) occurs when the rate of consumption at one trophic level results in a change in species abundance or composition at lower trophic levels. For example, a carnivore eats an herbivore (a direct interaction) and decreases its abundance, causing an indirect positive effect on the primary producer eaten by the herbivore. One example of a trophic cascade is the indirect regulation of U.S. Rocky Mountain meadow and forest communities by wolves, which were reintroduced into Lamar Valley in Yellowstone National Park in 1995. William Ripple and his colleagues at Oregon State University have studied this system extensively.

trophic cascade A series of trophic interactions within a food web in which the rate of consumption at one trophic level results in the change in species abundance or composition at lower trophic levels.

The simplified food web in Yellowstone National Park depicted in [Figure 56.3](#) shows that gray wolves in the park feed on elk, bison, and coyotes. Although they share some of these prey species with coyotes and grizzly bears, wolves exert particularly strong effects on the structure and dynamics of the community. We know this mostly because of how differently the community was structured in their absence, after wolves were hunted to extinction in Yellowstone in 1926. In the absence of wolves, the park service culled elk herds to prevent their populations from exploding. In 1968, in response to public pressure, the selective killing was stopped and the elk population rapidly increased ([Figure 56.9A](#)). The elk browsed aspen trees so intensely that the number of young trees recruited (added to the population) declined precipitously; once elk culling stopped, no new trees were recruited at all ([Figure 56.9B](#)). The elk also severely browsed streamside willows, with the result that beavers, which depend on willows for food, were mostly gone from Lamar Valley. In regions of the park where elk were absent, however, aspen and willow trees flourished. This observation suggested that the decline of the trees in Lamar Valley was indeed due to elk browsing rather than to climate conditions or other factors.

Figure 56.9 Wolves Initiated a Trophic Cascade in Yellowstone National Park (A) Number of elk in Wyoming's Yellowstone National Park. **(B)** Aspen recruitment (new trees) in the presence and absence of wolves.

Media Clip 56.2 **How Wolves Change Rivers** www.Life11e.com/mc56.2

In 1995, after wolves had been absent for 70 years, park managers reintroduced them to Yellowstone, and their population grew rapidly. The wolves preyed primarily on elk. The elk population of Lamar Valley dropped, and elk avoided the aspen groves, where they were especially vulnerable to wolf predation. Young aspen began to grow, willows regrew along streams, and the number of beaver colonies increased from one in 1996 to seven in 2003. Thus the presence or absence of a single predator influenced not only populations of its prey but also, indirectly, its prey's food resource and other species that depended on that resource. It is clear that wolves have a dramatic effect on the structure of meadow and forest communities through the trophic cascade they create.

Strongly interacting species often regulate community structure

The example of wolves in Yellowstone National Park offers clear evidence that species interactions vary considerably in their strength and direction, influencing the structure of communities. Some species have strong negative or positive effects on community structure, while others may have almost no effect at all. We can measure the **interaction strength**, or the effect of one species on the abundance of another species, by experimentally removing the "interactor" species and observing the response of the "target" species. If removing the interactor species causes a sharp decline in the population of the target species, we know that the interaction is a strong positive one. Alternatively, the interaction is strongly negative if the removal results in a large increase in the target species. If the removal has little or no effect on the abundance of the target species, then there is no interaction.

interaction strength A measure of the effect of one species (the interactor) on the abundance of another species (the target species).

Some species can have strong negative effects on a community by excluding or diminishing populations of other species through competition for limiting resources. As discussed in [Key Concept 55.3](#), competition is often asymmetrical: one species can be more negatively affected by the interaction than another. Asymmetrical competition leads either to competitive exclusion of the more negatively affected species (resulting in fewer species in the community than would be predicted by environmental conditions or dispersal alone) or to various mechanisms that promote coexistence, such as [*resource partitioning](#).

Competition among species can also be mediated by factors that affect the dominant species' ability to acquire resources, so-called [resource-mediated coexistence](#). For example, if events in the physical environment such as disturbance or stress affect the growth or survival of a dominant species, competitively inferior species may gain access to limiting resources. We will consider some specific examples of disturbance and stress in [Key Concept 55.4](#). Here we consider how those effects can influence community structure.

resource-mediated coexistence A type of coexistence among competitors in which factors such as disturbance, stress, or predation that act on the dominant competitor, allow inferior competitors access to limiting resources.

The [intermediate disturbance hypothesis](#) describes how varying degrees of disturbance (an abiotic process that injures or kills individuals) affect species diversity in communities ([Figure 56.10](#)). Joseph Connell, the author of the classic work on barnacle competition (see [Key Concept 55.3](#)), noted that the level of disturbance (both frequency and intensity) experienced by a community could have strong effects on its species diversity. He hypothesized that species diversity would be greatest in communities with intermediate disturbance and lowest in communities with low or high disturbance. At low levels of disturbance, competition from dominant species would lead to competitive exclusion of the inferior species, resulting in lower species diversity in the community. At the other extreme, a major disturbance would cause high mortality rates, leading to the extinction of some species in the community and resulting in lower species diversity. At intermediate levels of disturbance, species diversity would be greatest because (1) the influence of the dominant species is reduced by the disturbance, allowing the subordinate species to coexist, and (2) the mortality rates are not as high, so extinction events are less likely to occur.

intermediate disturbance hypothesis A hypothesis describing how varying degrees of disturbance (or stress or predation) affects species diversity within communities. Species diversity is greatest at intermediate levels of disturbance because competitive exclusion at low levels of disturbance and mortality at high levels of disturbance reduces species diversity.

Figure 56.10 The Intermediate Disturbance Hypothesis Species diversity is expected to be greatest at intermediate levels of disturbance (an abiotic process that injures or kills individuals).

Three other types of species that have large effects on community structure are considered below.

KEYSTONE SPECIES

As described in [Key Concept 55.2](#), **keystone species** can have strong community-wide effects, not because of their size or abundance but because of the important role they play in communities ([Figure 56.11](#)). Keystone species mostly act by creating trophic cascades. For example, top predators such as wolves and sea stars are keystone species because they have a large influence over community species richness, abundance, and composition, even though keystone species may be small in size and their abundance is relatively low.

keystone species Species that have strong community-wide effects despite their small size and abundance.

Figure 56.11 Keystone versus Foundation Species Species that have large effects on their communities do so by virtue of their relative size and abundance.

Sea otters (*Enhydra lutris*) that inhabit kelp forests on the west coast of North America illustrate how important keystone species can be in regulating community structure. Sea otters feed on sea urchins (*Strongylocentrotus* spp.), which feed on kelp, establishing a trophic cascade. Without predation by sea otters, sea urchin populations can explode, resulting in voracious consumption of kelp. Stretches of nearshore habitat that become nearly devoid of kelp beds, called “urchin barrens,” can no longer support the diversity of life that is supported when kelp habitat is present.

FOUNDATION SPECIES

Some strongly interacting species are capable of providing habitat and food for other species. These **foundation species** have a large effect on communities as a consequence of their large size or great abundance (see [Figure 56.11](#)). Trees are a good example of foundation species. For example, fig trees in tropical forests provide physical habitat for several thousand species of insects, non-avian reptiles, birds, and rodents in their canopy. Fig trees also serve as an important food source for species by producing fruits several times every year, especially at times when few, if any, other trees are fruiting. Dozens of frugivores depend on figs when no other fruits are present. Fig-eating animals include fruit bats, parrots, toucans, pigeons, flycatchers, trogons, orioles, rodents, howler monkeys, and even fish, which eat figs that fall into nearby streams. All of these animals represent prey for a diverse community of predators.

foundation species A species that has large, community-wide effects as a consequence of its large size and abundance, and its provision of habitat or food for other species.

ECOSYSTEM ENGINEERING SPECIES

Some species are specifically known for creating, modifying, or maintaining physical habitat for themselves and other species. These **ecosystem engineering species** can be either keystone or foundation species. These are species whose primary effect is to engineer the physical environment (rather than providing food), and they do not necessarily have great size or abundance in the community. For example, beavers create new habitats by cutting down (and killing) trees and using them to dam streams and create ponds and wetlands that provide habitat for species that would otherwise be unable to live in the area ([Figure 56.12](#)).

ecosystem engineering species Species that create, modify, or maintain physical habitat for themselves and other species, and can be keystone or foundation species as well.

Figure 56.12 Beavers Are Ecosystem Engineers By damming streams, beavers created networks of different types of wetlands (shown in red) in a 45-square-kilometer watershed on Minnesota's Kabetogama Peninsula, thus increasing species diversity in the region.

Species with similar effects on one another may coexist by chance

We have thus far discussed instances in which communities are composed of a few strongly interacting species and many weakly interacting species. But sometimes species in a community have relatively similar effects on one another. How is species diversity maintained when species vary little in their ability to obtain resources?

Over the last few decades, ecologists have proposed and tested so-called **lottery**, or **neutral models** that emphasize the role of chance in the maintenance of species diversity. Like the name suggests, these models assume that when resources are made available, they are used at random by individuals of different species who happen to be in the "right place at the right time." As long as all individuals have similar chances of obtaining resources (or "winning the lottery"), and no clear advantage in population growth, then their presence in the community should be maintained by chance events that free up resources for individuals competing for those resources. If there is a large disparity among species in their ability to obtain resources, the dominant competitor will always have a greater chance of obtaining resources and will eventually monopolize them. So for lottery models to work, the element of equal chance for all individuals to obtain resources is paramount to coexistence.

lottery model A hypothesis proposing that species diversity in communities is maintained by a "lottery" in which resources, made available by the effects of disturbance, stress, or predation, are captured at random by individuals of different species. Also called neutral model.

neutral model See lottery model.

The role of chance in maintaining species diversity, especially in unpredictable environments, has intuitive appeal. As long as individuals of species win the lottery every once in a while, they will continue to reproduce and grow their population. Lottery models have most often proven useful when applied to highly diverse communities such as coral-reef fishes and tropical rainforest trees, where hundreds of species overlap in their resource requirements ([Figure 56.13](#)).

Figure 56.13 Lottery Models Emphasize the Role of Chance Highly diverse tropical rainforests have hundreds of tree species that overlap in their resource requirements. As long as all individuals have similar chances of obtaining those resources (or “winning the lottery”), and no clear advantage in population growth, then their presence in the community should be maintained by chance events.

Ecologists are pursuing various and sometimes conflicting hypotheses to explain why certain species coexist in space and time. It is unlikely that any one theory can provide a wholly satisfactory explanation of the mechanisms that drive structure in all communities.

56.3 recap

Communities are complex networks of direct and indirect species interactions that vary in strength and direction. Strongly interacting species such as keystone species, foundation species, and ecosystem engineering species often regulate community structure through their interactions with other species. In communities where species interactions are more equivalent, chance plays a greater role in determining community structure.

learning outcomes

You should be able to:

- Describe, analyze, and give examples of the importance of indirect interactions in forming and maintaining community structure.
- Explain the term “trophic cascade” as it relates to indirect interactions in communities.
- Define and compare keystone and foundation species, giving examples of each.
- Define a lottery, or neutral, model in community ecology, and describe its usefulness in

explaining the chance occurrence of species in a community.

1. Suppose wolves were once again excluded from Yellowstone National Park. What direct and indirect interactions would change, and how would this affect aspen forests?
2. Make an argument for why beavers could be considered ecosystem engineering species and keystone species but not foundation species.
3. Using the lottery model as your guide, explain how species that depend on the same set of limiting resources can coexist.

When Mount St. Helens erupted in 1980, it was clear that the surrounding ecological communities would change forever. Change is a regular feature of all communities, but not all changes are as dramatic as those involving a volcanic eruption. In the next section we will consider how both subtle and catastrophic factors change communities over time.

***connect the concept** As you saw with the bee-shin dagger agave example, resource partitioning, or the sharing of limiting resources by using them in different ways, is one way that species may reduce intense competition and coexist. See [Key Concept 55.3](#).

56.4 Communities Are Always Changing

Imagine that you could look back in time and observe the change in a typical forest on Mount St. Helens ([Figure 56.14](#)). Over the last few decades, you would have seen both subtle and catastrophic changes. Subtle changes would involve a slow replacement in species composition as a consequence of competition, predation, and facilitation. More catastrophic changes would include volcanic eruptions and deforestation, resulting in the destruction of some species and replacement with others over time. The community at any one time is the result of these various changes both natural and human-caused.

Species interactions, such as competition, herbivory, and disease, can cause the gradual replacement of species over time.

Changes in abiotic conditions, such as temperature or rainfall, can cause physiological stress, and eventually mortality.

Catastrophic disturbances, such as the eruption of Mount St. Helens or clearcuts, can cause massive injury and death in forests.

Figure 56.14 Changes on Mount St. Helens Forest communities on Mount St. Helens have experienced significant changes over hundreds of years. The types of change have been both subtle and catastrophic.

focus your learning

Community succession is caused by factors that induce change, including disturbance and/or stress.

Communities recover from a disturbance through the process of succession, which results in a climax community.

Primary succession occurs after a catastrophic disturbance whereas secondary succession occurs after a disturbance when most but not all organisms have been destroyed.

Successional changes in a community are not necessarily predictable or repeatable, and may result in alternative states.

Change in communities can be caused by abiotic and biotic factors

How a community changes in species composition over time is known as [succession](#).

Succession is the result of both abiotic (physical and chemical) and biotic factors.

succession The gradual, sequential series of changes in the species composition of an ecological community following a disturbance.

A [disturbance](#) is an abiotic event that physically or chemically injures or even kills some individuals, creating opportunities for other individuals to grow and/or reproduce. Some ecologists also consider biotic events, such as elephants trampling vegetation or beavers felling trees, to be disturbances. The magnitude of a disturbance can vary enormously. Many disturbances are limited to small areas—for example, a log carried by waves may crush algae and animals on a rocky shore. In contrast, hurricanes, forest fires, and volcanic eruptions can affect communities over hundreds or thousands of hectares. Although small-scale disturbances are far more frequent, the occasional large-scale event is often responsible for most of the changes in a community. For example, a single volcanic eruption on Mount St. Helens felled many more trees than multiple storm events ever did, even over decades.

disturbance An abiotic event that physically or chemically injures or kills some individuals, creating opportunities for other individuals to grow and/or reproduce. (Contrast with stress.)

[Stress](#), in contrast to disturbance, occurs when some abiotic factor reduces the growth, reproduction, and/or the survival of some individuals. A common stress on the mountain communities of Mount St. Helens is the effect of temperature on the growth and reproduction of plants. As temperatures decrease with increasing elevation on the mountain, you might expect plants at higher altitudes to experience more stress than those at lower altitudes. But as illustrated in [Figure 55.14](#), the stress that alpine plants experience at higher elevations can be tempered by the presence of neighboring plants. That is, some types of interactions can mitigate the effects of stress.

stress An abiotic factor that reduces the growth, reproduction, and/or the survival of some individuals. (Contrast with disturbance.)

Biotic factors can influence community change as well. On Mount St. Helens, change might be driven by competition between different tree species, with the most dominant tree species

surviving over time (see [Figure 56.14](#)). Herbivory by elk is another example of a species interaction that can initiate change. By preferentially browsing on certain species such as willow and aspen, elk can shift the trajectory of plant community succession from forest to meadow, as happened in Yellowstone National Park (see [Figure 56.9](#)).

Succession is a process of change in communities over time

Traditionally ecologists have viewed succession as a progression of stages in which species come and go until a climax community arises. The [climax community](#) is thought to be a stable assemblage of species that experiences little change until an intense disturbance wipes out the community, sending it back to its initial stages again. As you will see later in this section, whether some communities reach a true stable end point is questionable. Let's consider the mechanics of succession in more detail.

climax community The final stage of succession; a community that is capable of perpetuating itself under local climatic and soil conditions and persists for a relatively long time.

Succession is probably most easily observed after a catastrophic disturbance kills all the organisms in a community, leaving an environment devoid or nearly devoid of life. This type of change is known as [primary succession](#). Glaciers, volcanic activity, and in some cases floods or landslides cause disturbance that initiates primary succession. Primary succession by its very nature can be slow because the early arrivals (known as [pioneer](#) or [early successional species](#)) must deal with extreme conditions. Many pioneer species deal with these conditions by employing certain [*life history strategies](#) or species interactions to their favor.

primary succession Succession of ecological communities that begins in an area devoid of life, such as on recently exposed glacial till or lava flows. (Contrast with secondary succession.)

pioneer species Species that arrive first to primary successional habitats and must deal with extreme conditions; they tend to have life history strategies that maximize population growth (see *r*-strategists). Also called early succession species.

early successional species See pioneer species.

One of the best-known examples of primary succession is that seen in plant communities in the wake of the retreat of glaciers in Glacier Bay, Alaska ([Figure 56.15A](#)). Captain George Vancouver first recorded the location of glacial ice there in 1794, while exploring the west coast of North America. Over the last 200 years, the glaciers have retreated up the bay, scraping the landscape down to bare rock and leaving a series of moraines—gravel deposits dropped where the glacial front was stationary for a number of years. No human observer was present to observe changes over the entire 200-year period, but ecologists have inferred the temporal pattern of succession by studying the vegetation on moraines of different ages ([Figure 56.15B](#)). The youngest moraines, closest to the current glacial front, are populated with bacteria, fungi, and photosynthetic microorganisms that can support themselves on bare rock. Slightly older moraines farther from the glacial front are home to pioneer communities containing lichens, mosses, willows, and cottonwoods, which break down rocks and, when they die, decompose and contribute to the buildup of soil. Mosses and a few species of shallow-rooted shrubs in the genus *Dryas* eventually become established and contribute to soil building as they die and decompose. Still farther from the glacial front, successively older moraines have deeper soil

layers that support shrubby willows and alder trees. Finally, a century after glacial retreat, a mature Sitka spruce forest dominates, fostering a diverse array of forest species.

Figure 56.15 Succession in Glacier Bay, Alaska (A) Over more than 200 years, the melting of glaciers has exposed bare rock and glacial moraines to colonization and succession. **(B)** As the community occupying a glacial moraine changes from an assemblage of pioneer plants such as *Dryas* to a spruce forest, soil depth increases and nitrogen accumulates in the soil.

Q: Based on the locations of the glaciers over time, indicate where the oldest and youngest communities (black dots) are located.

Animation 56.1 **Primary Succession on a Glacial Moraine**

www.Life11e.com/a56.1

Nitrogen is virtually absent from glacial moraines, so the plants that grow best on recently formed moraines at Glacier Bay are *Dryas* and alders, both of which have nitrogen-fixing bacteria in nodules on their roots (see [Figure 35.6B](#)). Nitrogen fixation by these plants improves the soil so that spruce trees can grow (see [Figure 56.15B](#)). Spruces then outcompete and displace the early colonists. If the local climate does not change dramatically, a climax community dominated by spruce trees is likely to persist for many centuries on old moraines at Glacier Bay.

On Mount St. Helens, ecologists have had a unique opportunity to study primary succession from its inception. As described in the opening story, the alpine communities surrounding the lava dome experienced the greatest destruction; they were the first to be hit by an avalanche of mud and hot water and then pelted by hot, sterilizing pumice. This created the so-called Pumice Plain, an area completely lacking life, including any traces of organic matter. The first plant species to arrive, a year after the eruption, was the dwarf lupine (*Lupinus lepidus*). Dwarf lupines, like *Dryas* and alders, utilized the nitrogen produced by bacterial symbionts in root nodules to colonize the sterile environment of the Pumice Plain. They subsequently facilitated

other species of plants by trapping seeds and detritus and increasing the overall nutrient content of the soil. By providing safe sites for seedlings to become established, the dwarf lupines greatly increased the rate of primary succession on Mount St. Helens. Because of the early inroads made by dwarf lupine, researchers documented roughly 20 plant species living on the Pumice Plain 20 years after the eruption.

A surprising discovery about primary succession on Mount St. Helens was the important role of animals in directing change. For example, scientists observed that newly formed and isolated ponds and lakes were colonized by amphibians at a faster rate than one might predict given the surrounding harsh conditions. Ecologists discovered that frogs and salamanders were using tunnels created by the northern pocket gopher (*Thomomys talpoides*) as refuges when they made their way from pond to pond across the dry landscape ([Figure 56.16](#)). Pocket gophers successfully survived the eruption by living in tunnels under the mud. They also benefitted by the expansion of their preferred habitat—grassy meadows—after the eruption. Pocket gophers facilitated plant succession through their burrowing activities, which brought to the surface organic matter, seeds, and fungal spores buried deep under the pumice.

Figure 56.16 Pocket Gophers to the Rescue The burrowing activity of northern pocket gophers, some of which survived the eruption underground, resulted in tunnels that amphibians used to move from one pond to another. It also brought organic matter, seeds, and fungal spores to the soil surface, creating microhabitats, like this one in the Pumice Plain, where plants can grow.

Q: Are pocket gophers keystone species, foundation species, and/or ecosystem engineering species?

The other type of succession, known as [secondary succession](#), involves the

reestablishment of a community when most, but not all, organisms have been destroyed. Secondary succession is often initiated by human activities (such as clear cutting) as well as by natural disasters (such as storms and fires). Secondary succession is more common and it progresses more rapidly than primary succession. For example, even though the eruption of Mount St. Helens completely destroyed some areas near the blast zone, there were large areas where organisms survived and secondary succession took place.

secondary succession The reestablishment of a community when most, but not all, organisms have been destroyed. (Contrast with primary succession.)

Ecologists compared primary and secondary succession on Mount St. Helens by following small mammals in the community. As we mentioned in the chapter opening, different Mount St. Helens communities experienced different levels of disturbance from the eruption. **Investigating Life: Rising from the Ashes** describes research by Charles Crisafulli and colleagues at the USDA Forest Service, showing that the recovery of small mammal populations on Mount St. Helens varied significantly between primary and secondary successional habitats. The Pumice Plain (primary successional habitat completely devoid of life after the eruption) had the lowest species richness of small mammals, a pattern that persisted for at least 20 years. In contrast, small mammal populations recovered relatively quickly in the Blowdown Zone and the Tephra-fall Zone (secondary successional forest in which some life survived under downed trees and ash fall). In fact, within a few years, the number of small mammals in these two zones was similar to that in the undisturbed reference area 21 kilometers away. This comparison makes clear that the starting conditions characterizing secondary succession are critical in giving communities a “head start” in their recovery.

Rising from the Ashes

experiment

Original Paper: Crisafulli, C. M., J. A. MacMahon and R. R. Parmenter. 2005. Small mammal survival and colonization on the Mount St. Helens Volcano: 1980–2002. Pp. 199–218 in V. H. Dale, F. J. Swanson and C. M. Crisafulli, eds. *Ecological Responses to the Eruption of Mount St. Helens*. New York: Springer.

Charles Crisafulli and his colleagues were some of the first ecologists to study the successional processes on Mount St. Helens after the eruption. They concentrated on the recovery of small mammals in three types of communities that the eruption had disturbed in different ways: a primary successional community named the Pumice Plain, which experienced complete destruction of all living things, and two secondary successional communities: the Blowdown Zone, in which trees fell and the area was covered in mud but some life remained underground, and the Tephra-fall Zone, where the intact forests and meadows were covered in volcanic debris. An undisturbed reference area, 21 kilometers away from the mountain, was used as a control. To compare the initial survival and subsequent recovery of small mammals in primary versus secondary successional communities, the researchers conducted extensive trapping between 1982 and 2000 at several locations on Mount St. Helens and in the reference area.

HYPOTHESIS ▶ As a result of the variation in disturbance from the eruption, the primary successional community will have lower mammal species richness than the secondary successional communities, or the reference area, both initially and through time.

METHOD

1. Starting in 1982, several sites were established in the reference area and in three volcanically disturbed areas (Pumice Plain, Blowdown Zone, and Tephra-fall Zone). Trapping sessions were conducted at the sites up to four times a year, from June to October.
2. At each site, live traps baited with rolled oats and peanut butter were set up in multiple plots in a grid pattern. To capture northern pocket gophers, which remain underground, PVC pipe traps were constructed and placed in their burrows.
3. During a trapping session, the traps were checked each morning. Captured animals were identified, uniquely marked, weighed, examined to determine sex and reproductive conditions, and released.

(continued)

RESULTS

Early trapping efforts showed that a total of 17 species of small mammals survived the eruption with most located in the reference area. Over time, small mammal species richness increased in all the communities but proportionally more so in the Blowdown and Tephra-fall Zones (see graph). By 2000, the two secondary successional communities had species richness values roughly equivalent to those in the reference area. The Pumice Plain had only one year (1987) when more than one species of small mammal was present.

CONCLUSION Numerous small mammal species survived and thrived in the post-eruption secondary successional communities of Mount St. Helens. In comparison, the primary successional community showed little recovery of small mammal richness over the 20-year period.

work with the data

In addition to examining small mammal species richness, Crisafulli and his team were interested in the composition of those species and their abundance—data that could give them additional insights into the processes important to the species' recovery (or lack thereof). Below are capture data from 2000 on the small mammal species composition and proportional abundance in the four different post-eruption communities.

Small mammal species	Proportion of individuals			
	Pumice Plain	Blowdown Zone	Tephra-fall Zone	Reference area
Deer mouse (<i>Peromyscus maniculatus</i>)	1.00	0.20	0.25	0.10
Yellow-pine chipmunk (<i>Tamias amoenus</i>)	0	0.40	0	0
Cascade golden-mantled ground squirrel (<i>Spermophilus saturatus</i>)	0	0.05	0	0
Creeping vole (<i>Microtus oregoni</i>)	0	0.10	0	0
Shrew mole (<i>Neurotrichus gibbsii</i>)	0	0.05	0	0
Trowbridge's mole (<i>Sorex trowbridgii</i>)	0	0.10	0	0.05
Montane shrew (<i>Sorex monticolus</i>)	0	0.10	0.15	0.10
Southern red-backed vole (<i>Clethrionomys gapperi</i>)	0	0	0.45	0.65
Townsend's chipmunk (<i>Tamias townsendii</i>)	0	0	0.05	0
Ermine (<i>Mustela erminea</i>)	0	0	0.05	0
Northern flying squirrel (<i>Glaucomys sabrinus</i>)	0	0	0.05	0
Vagrant shrew (<i>Sorex vagrans</i>)	0	0	0	0.05
Northern water shrew (<i>Sorex palustris</i>)	0	0	0	0.05

QUESTIONS►

1. Using the data in the table above, calculate the species diversity of each of the post-eruption communities using the Shannon index (see Table 56.1). Which community has the lowest species diversity and which has the highest? How does this pattern compare with that of the species richness values for the four communities?
2. Plot species diversity versus the degree of disturbance from the eruption for the four communities. How well do the data fit the intermediate disturbance hypothesis (see Figure 56.10)? Explain.
3. Consider the presence or absence of particular species in the four communities. Which species is present in all the communities? What does that suggest about its life history?
4. The Blowdown Zone, Tephra-fall Zone, and reference area all have similar species richness (7, 6, and 6 species, respectively), but how do they compare in terms of species composition? Do they appear to be similar? If not, why do you think this is the case?

A similar **work with the data** exercise may be assigned in **LaunchPad**.

Both facilitation and inhibition influence succession

The progress of succession greatly depends on the activity of successive colonists, each of which modifies the environment to either facilitate or inhibit the colonization by other species. Facilitation is seen, for example, in the fixation of nitrogen by *Dryas* and alders that allows spruce trees to become established in Glacier Bay (see [Figure 56.15B](#)). At later stages of succession, though, competition by spruce trees for nitrogen, light, and water inhibits other tree species from establishing themselves. Likewise, dwarf lupines helped facilitate the establishment of later successional plants but, in turn, were inhibited by multiple insect herbivores, which were able to control the pace of primary succession.

Why do we see this interplay between facilitation and inhibition as succession progresses? In most post-disturbance successional sequences, the early pioneer species are exposed to physically challenging conditions that can be tolerated only with the help of other species. For example, in secondary succession, many of the first organisms to arrive on bare soil after a disturbance are detritivores, which process dead organic matter and release nutrients, thus facilitating the establishment of early colonizing plants. Early successional species that can disperse to these habitats and tolerate and modify the abiotic environment will likely facilitate other species without those capabilities. As succession progresses, species that are less stress-tolerant but are larger, longer-lived, and competitively superior will likely come to dominate as the conditions improve, inhibiting earlier pioneer species. While there is typically a transition from early facilitation to later inhibition in most successional sequences, as species diversity increases, a variety of both positive and negative interactions naturally arise, further shaping the pattern of succession.

Alternative successional pathways result in variations in community composition

The trajectory of succession in any community is not necessarily a repeatable and predictable process. Succession often occurs over long periods of time—longer than the life span of any one researcher—making it hard to know whether the changes in species composition are repeatable over time. For example, suppose dwarf lupines had not successfully colonized the Pumice Plain of Mount St. Helens because of intense herbivory. Might later successional stages, such as growth of Douglas fir forests, never develop? Possibly. What is the chance that different, alternative communities could be established after a similar disturbance? Ecologists use the term [alternative states](#) to refer to the different community assemblages that could develop at the same location under similar environmental conditions.

alternative states Different community assemblages that develop at the same location under similar environmental conditions.

The theory behind alternative states can be visualized by imagining a landscape full of valleys, each of which represents a different community type or state ([Figure 56.17A](#)). Imagine, for example, valleys on the Pumice Plain of Mount St. Helens, each of which represents a community that might potentially form there. Impose upon this landscape changes in local conditions—such as the presence or absence of a particularly strongly interacting species—that might influence a community to migrate out of one valley (or state) and into another ([Figure 56.17B](#)). Intense grazing by herbivores could, for example, influence where dwarf lupine become established on the Pumice Plain. If lupine does not become established in a “new” valley, a different successional trajectory may be established, leading to an alternative state for the community. Now, what if conditions change again, and revert back to those of the initial state? Interestingly, even if original conditions are restored, the community may not revert to the initial state. If the change experienced by the original community was sufficiently large, the

successional trajectory of the community can be irrevocably changed ([Figure 56.17C](#)). For example, removing herbivores from the system might not bring back dwarf lupine. The system is said to show **hysteresis** when the community is unable to shift back to its initial state even when the original conditions are restored.

Figure 56.17 Alternative States (A) A community is represented by a ball that moves within a landscape of community states (valleys). (B) In this analogy the valleys are shallower or deeper according to the magnitude of change (ΔX) needed to shift the community from one state to another. (C) Hysteresis occurs when reversal of the change ($-\Delta X$) does not return the community to its original state.

hysteresis The inability of a community that has undergone change to shift back to the initial community type, even when the original conditions are restored.

Communities that have undergone alternative states, or what are sometimes called regime shifts, have become increasingly of interest as it becomes clear that human activities, such as habitat destruction, species introductions, and overharvesting, are shifting communities to alternative states. Once communities have shifted to a new regime it is often unclear whether the original community can be restored or whether hysteresis will occur. Reintroducing wolves to Yellowstone National Park did successfully result in the recolonization of aspens as a consequence of elk population control (see [Figure 56.9](#)). But will protection of sea otters populations help reestablish kelp forests? Will Atlantic Ocean and Caribbean coral-reef fish communities recover if lionfish are eradicated there (see [Chapter 55](#), Investigating Life: The Lionfishes King)? These are questions whose answers may be found in better understanding the factors that drive alternative states and the role that restoration plays in reversing the effects of those factors.

56.4 recap

Communities constantly undergo change in species composition over time as a result of abiotic and biotic factors, a process known as succession. Abiotic-induced changes to communities come in two forms: disturbance and stress. There are two types of succession: primary succession is the recovery of a community after a catastrophic disturbance kills all the organisms in it, and secondary succession is the reestablishment of a community when most, but not all, organisms have been destroyed. Both facilitation and inhibition influence succession. Communities under similar environmental conditions are sometimes subject to

alternative successional pathways, leading to variations in community composition (alternative states).

learning outcomes

You should be able to:

- Distinguish between disturbance and stress, and give examples of each.
 - Given specific examples, characterize biotic factors that might influence community structure, and describe their possible effects.
 - Describe, with examples, the conditions required for primary succession to occur, including the time intervals involved.
 - Describe, with examples, the concept of alternative states, or regime shifts, in a community, including how such states might arise.
-

1. What is the difference between disturbance and stress?
2. What are some biotic factors that induce change in communities?
3. True or false? "Primary succession is controlled only by facilitation." Explain your answer.
4. How does an alternative state, or regime shift, occur? Give an example from the chapter of such a shift.

We have focused thus far on the dynamic nature of community structure and on the factors on which community membership depends. In the next section we will consider whether the successful functioning of communities depends on the number of species they contain. In other words, how does species richness affect community productivity and stability?

***connect the concept** Life history strategies are the lifetime patterns of growth, reproduction, and survival of a species (see [Key Concept 54.3](#)). Pioneer species tend to have life history strategies that maximize population growth (*r*-strategists).

56.5 Relationships between Species Diversity and Community Function Are Often Positive

As more and more species have either become extinct or are threatened with extinction, ecologists are increasingly interested in understanding what a loss in species diversity means for communities and the way in which they function. Let's next consider research designed to understand how species diversity affects communities as well as agricultural crops.

focus your learning

Community function can be measured by stability, which is associated with species richness. Polycultures are used to test the relationship between diversity, productivity, and stability.

Community function describes the way a community works and can be measured using metrics such as plant productivity, soil fertility, or water availability. Another measure of how well a community functions is its resistance to (or recovery from) disturbance, known as its **stability**. Ecologists have hypothesized that communities with more species function better than communities with fewer species. The argument is that no two species in a community use resources in exactly the same way such that a community with more species will show more complete and efficient resource use. Also, should environmental conditions change, a species-rich community is more likely to contain some species that can persist under the new conditions. Thus a species-rich community should be more stable—that is, less likely to change over time in either productivity or species composition—than a species poor community. Let's examine these assumptions with some experiments.

community function The way a community works as measured by metrics such as plant productivity or stability.

stability The resistance of an ecological community to (or recovery from) a disturbance.

Species diversity is associated with productivity and stability

To test the hypothesis that species-rich communities are more stable than species-poor communities, David Tilman and his colleagues at the University of Minnesota cleared 120 outdoor plots, in which they planted grasses in mixtures ranging from 1 to 24 grass species. At the end of each growing season, they measured total plant cover (a measure of grass biomass, and thus of net primary production) and the population densities of all the grasses in each plot. Over a period of 11 years, which included a serious drought, the plots with more species were more productive (**Figure 56.18A**), and their productivity was less variable from year to year. These findings were consistent with the hypothesis that species richness promotes productivity and keeps productivity stable. Moreover, in the plots with greater species richness, soil nitrogen was used more efficiently (**Figure 56.18B**). However, the population densities of *individual* species in the plots were not stable over the years (regardless of a plot's species richness) because different species performed better during drought years and wet years. In other words, higher species richness increased the stability of plant production in the plots, but not the

stability of their species composition.

Figure 56.18 Species Richness Enhances Community Productivity David Tilman and his colleagues cultivated a total of 120 grassland plots, containing from 1 to 24 grassland species, for 11 years. **(A)** Total plant cover (a measure of grass biomass, and thus of net primary production). **(B)** The amount of nitrogen remaining in the soil is a measure of resource use efficiency.

Researchers continue to debate whether species diversity is responsible for maintaining stability or is simply correlated with stability. This question is important because many of the alterations that humans have made in the structure of natural communities have reduced their species richness, and many of these human-altered communities—notably agricultural communities—are notoriously unstable.

Diversity, productivity, and stability differ between natural and managed communities

Although ecologists have been debating the relationships among species diversity, productivity, and stability for only a few decades, humans have been experimenting with those relationships, albeit inadvertently, for millennia—since plants were domesticated and agriculture was invented. Since the dawn of agriculture, crops have been susceptible to diseases and insect outbreaks: massive (often sudden) increases in populations of species that destroy or damage crops.

The practice of growing crops as **monocultures**—plantings of a single crop species—is one

reason why managed agricultural communities are particularly unstable. Most farmers have little tolerance for the presence of any potential competitors for their crops and actively eliminate weeds (and the herbivore species that live with them) from their fields. Thus a typical agricultural community has very low species diversity. So the answer to the question of whether diversity causes or is merely correlated with stability may be sought in modern farming practices. The predisposition of agricultural communities to play host to outbreaks may well result from human influences on community structure.

monoculture In agriculture, a large-scale planting of a single crop species. (Contrast with polyculture).

For the last 20 years, ecologists have been using traditional subsistence agricultural plots as experimental models for testing the relationships between diversity and stability. Throughout the world, many farmers with small land holdings grow **polycultures** or multiple crops on the same plot. In Costa Rica, farmers often grow corn together with sweet potato. Such corn-sweet potato dicultures contain fewer sweet potato pests and more parasitoid wasps (which feed on those pests) than do sweet potato monocultures. Wasps feed on the corn pollen, and the tall corn plants act as a structural barrier, shade plant, and source of disruptive chemical signals that interfere with the ability of the sweet potato pests to find their host plants.

polyculture In agriculture, a large scale planting of multiple crop species. (Contrast with monoculture.)

Recently, such applications of community ecology have been paying dividends. Although monoculture is overwhelmingly the dominant agricultural practice, polycultures are under development for agricultural production systems as varied as carp and shrimp farming, vermicomposting (raising worms for compost), and biofuel feedstock production.

56.5 recap

Studies show that the relationships between species diversity and community function (measured as productivity and stability) are often positive. Species diversity enhances productivity because species use resources in slightly different ways; mixtures of species tend to result in a more complete use of limiting resources. Species diversity is hypothesized to enhance stability (a measure of resistance to, or recovery from, disturbance) because the more species a community contains, the more likely some species can persist under variability. These species diversity-community function relationships can be used in agricultural settings to increase crop productivity.

learning outcomes

You should be able to:

- Describe how and why growing polycultures can increase agricultural productivity.

1. Why do Costa Rican farmers often grow multiple crops on the same plot, and why might this be a good strategy under drought conditions?

Q How have ecological communities on Mount St. Helens responded to the eruption, and what processes have been important to their recovery?

A similar question was asked by a group of ecologists who convened a week-long field camp on the twentieth anniversary of the eruption in 2000. Many of the participants had spent their entire careers studying the successional patterns on the disturbed landscapes of the mountain. When they left, they agreed to write a book, and 5 years later *Ecological Responses to the 1980 Eruption of Mount St. Helens* was published. The book offers unique insights into the successional processes that communities undergo. One important discovery was that the eruption created disturbances that varied in their effects both on the survival of organisms and their subsequent recovery. Because the eruption occurred in spring, many species were dormant under the winter snows and were able to survive the initial eruption. The recovery of some dormant species such as small mammals has been surprisingly quick. A second important discovery was the role that survivors played in controlling the pace and pattern of succession. Unlikely alliances were formed that hastened succession, as you saw with the northern pocket gopher and amphibians. Finally, the researchers realized that multiple mechanisms were responsible for the pattern of succession on Mount St. Helens. Dispersal, abiotic conditions, and species interactions all played a role in the successional process. The variety of ways in which species responded, and the resulting community assemblages, surprised the ecologists lucky enough to have studied the rise of these communities from the ashes.

Future directions

Despite decades of data and discoveries, research on Mount St. Helens has just begun. Will communities there follow paths of succession that are predictable and repeatable? Or will they form alternative states that are highly dependent on their historical legacies? Unfortunately, succession is a long process spanning many lifetimes of scientists. Steps have been taken to continue the “succession” of research on Mount St. Helens. One of the first steps was to secure Mount St. Helens, in 1982, as a National Volcanic Monument dedicated to research, recreation, and education. This designation, along with coordinated research funding, has set the foundation for long-term study sites and data collection and preservation. In addition, the early “pioneer” scientists have cultivated a strong collaborative culture that brings together young scientists who study different levels of biological organization—from molecules to ecosystems. The collaboration is renewed periodically with “science pulse” camps—week-long events attended by dozens of scientists from around the world who gather benchmark data on a diversity of plants, animals, and microbes. Around the campfire at night, the scientists share observations and recruit the next generation of those who will continue the scientific legacy and storytelling into the future.

► 56.1 Communities Are Groups of Interacting Species Occurring Together in Space and Time

- Communities vary in size and scope, and it is often impractical to define their boundaries. Ecologists often focus on a subset of species in a community based on similarities in taxonomy, resource use (**guilds**), function (functional groups), or trophic and energetic connections (**food webs**). [Review Figure 56.2](#)
- Food webs can be divided into **trophic levels** based on how groups of species interact and obtain energy. Food webs identify primary producers, **primary consumers** (herbivores), **secondary consumers** (carnivores), and so on. **Omnivores** feed on multiple trophic levels, and **detritivores** feed on the waste products and dead bodies of organisms. [Review Figure 56.3](#), [Activity 56.1](#)
- Species diversity** and composition are important descriptors of **community structure**. The **Shannon index** is a measure of species diversity that combines the number of species (**species richness**) and their relative abundances compared with other species (**species evenness**). [Review Figure 56.4](#), [Table 56.1](#), [Activity 56.2](#)
- Biodiversity** is a term used to span multiple scales of diversity, from genes to species to communities. [Review Figure 56.5](#)

► 56.2 Community Membership Depends on Species Supply, Environmental Conditions, and Species Interactions.

- The three basic factors responsible for community membership are (1) the regional species pool and dispersal ability (species supply), (2) physical and chemical environmental conditions (abiotic conditions), and (3) species interactions (biotic conditions). These three factors act as “filters” that exclude (or include) species in communities. [Review Focus: Key Figure 56.6](#)

► 56.3 Communities Are Complex Networks of Species Interactions That Vary in Strength and Direction

- Direct interactions** occur between two species. **Indirect interactions** occur when the direct relationships between two species are mediated by a third (or more) species. [Review Figure 56.8](#)
- A **trophic cascade** occurs when the rate of consumption at one trophic level results in a change in species abundance or composition at lower trophic levels. [Review Figure 56.9](#)
- Some species have especially strong negative effects on community structure, resulting in resource partitioning or **resource-mediated coexistence**. The **intermediate disturbance hypothesis** proposes that disturbance promotes species diversity, in part by reducing the negative effects of dominant competitive species. [Review Figure 56.10](#)
- Keystone species** influence community structure disproportionately to their size or abundance, producing trophic cascades. **Foundation species**, by providing food and habitat for other species, have a large effect on communities as a consequence of their large size or great abundance. **Ecosystem engineering species** affect community structure by creating, modifying, or maintaining physical habitat for themselves and other

species irrespective of their size or abundance. **Review** [Figures 56.11, 56.12](#)

- In communities where species interactions are more equivalent, **lottery**, or **neutral**, **models** propose that as long as all individuals have similar chances of obtaining resources, and no clear advantage in population growth, then their presence in the community should be maintained by chance events that free up resources for competing individuals.

▶ 56.4 Communities Are Always Changing

- communities constantly undergo change in species composition over time as a result of abiotic and biotic factors, a process known as **succession**. Disturbance and stress are two significant forms of abiotic-induced community change. A **disturbance** is an abiotic event that physically or chemically injures or kills individuals, whereas **stress** occurs when some abiotic factor reduces the growth, reproduction, or ultimately survival of individuals. **Review** [Figure 56.14](#)
- There are two types of succession: **primary succession** is the recovery of a community after a catastrophic disturbance kills all the organisms in it, and **secondary succession** is the reestablishment of a community when most, but not all, organisms have been destroyed. **Review** [Figure 56.15](#), [Animation 56.1](#), [Investigating Life: Rising from the Ashes](#)
- Facilitation and inhibition influence primary and secondary succession.
- The outcome of succession is not always predictable; alternative successional pathways, or regime shifts, lead to different community assemblages under similar environmental conditions. **Hysteresis** occurs when a community is unable to shift back to its original state even when the original conditions are restored. **Review** [Figure 56.17](#)

▶ 56.5 Relationships between Species Diversity and Community Function Are Often Positive

- Studies show that the relationships between species diversity and **community function** (measured as productivity and stability) are often positive. **Stability** is a measure of resistance to, or recovery from, disturbance. **Review** [Figure 56.18](#)
- Species diversity-community function relationships can be used in agricultural settings to increase crop productivity.

Review

- 6.3 Indirect interactions involving three or more species can affect species diversity and abundance in communities.
- 6.3 Keystone, foundation, and ecosystem engineering species have major effects on community structure.
- 6.4 Communities recover from a disturbance through the process of succession, which results in a climax community,
- 6.4 Successional changes in a community are not necessarily predictable or repeatable, and may result in alternative states.
- 6.5 Community function can be measured by stability, which is associated with species richness.

Original Paper: Alvarez-Filip, L., J. P. Carricart-Ganivet, G. Horta-Puga and R. Iglesias-Prieto. 2013. Shifts in coral-assemblage composition do not ensure persistence of reef functionality. *Scientific Reports* 3: 3486.

The calcium carbonate (CaCO_3) skeletons of stony corals form the basis for coral-reef community structure. As they build the reef, coral skeletons increase habitats for other reef species. Coral communities consist of coral species with two basic functional attributes. Coral species with high reproductive rates and relatively fast growth are more tolerant of environmental change, but these species tend to be small and do little to increase reef size or number of habitats. Massive corals that contribute the most to reef size and number of habitats are slower growing and are less tolerant of environmental change.

Corals are undergoing serious declines because of disease, pollution, and the effects of temperature and ocean acidification related to climate change. These declines can result in rapid changes in the composition of coral communities. As the pace of climate change escalates, changes in coral communities will likely increase.

Researchers developed simplified models consisting of four coral genera from the Caribbean to study the ability of coral reefs to retain functionality with changing species composition (**Figure A**). They looked at reef rugosity, which is a measure of reef complexity and habitat diversity, and calcification rate, which measures how fast coral skeletons are produced. Rugosity is calculated as a ratio of the contour of the reef relative to its length. A value of 1.00 equals a flat reef; larger values represent higher rugosity.

The table shows reef rugosity and estimated calcification rate for the four coral genera. **Figure B** shows how reef rugosity (dotted lines) and calcification rate (solid lines) would change in coral communities through time in two models: (i) steady coral cover decline from 45 to 10 percent (red lines) and (ii) steady coral recovery from 10 to 45 percent (blue lines).

Figure A

Porites	1.49	6.12
Agaricia	1.52	2.43

Questions

- Based on their functions in the reef community, are corals keystone, foundation, or ecosystem engineering species? Explain your answer.
- According to the table, which coral genera would be most important in building the coral reef and providing habitats for other species? Which genera would be least important? Why?
- In the graph, the red lines (model *i*) show how reef rugosity and calcification rate would change if coral cover declined from 45 to 10 percent. Which coral genera are likely declining most rapidly, and why? How and why would the loss of these genera be likely to affect reef function and community biodiversity?
- According to the graph, does model *ii* (blue lines), which shows how reef rugosity and calcification rate would change if coral cover increased from 10 to 45 percent, indicate that the reef is regaining its original functionality? On what do you base this conclusion? What factors might be affecting the reef's ability to regain its functionality?
- Are the two model coral-reef communities illustrated here undergoing succession? On what do you base your conclusion? Using the concept of alternative states, explain possible differences in coral-reef community structure as the reef recovers, and consider how such differences might affect the reef's function.

Food Webs in an Acidic and Warming Ocean

There is no dispute that the burning of fossil fuels over the last two centuries has increased Earth's atmospheric CO₂ concentrations. Estimates show that oceans are absorbing about 48 percent of all atmospheric CO₂. Marine primary producers use some of the human-caused CO₂ in photosynthesis, but the remainder reacts chemically with seawater, lowering its pH and causing oceans to become more acidic. Ocean acidification can have negative effects on calcifying organisms such as corals, mollusks, and crustaceans, which rely on calcium carbonate for the accretion and maintenance of their external shells. But the negative effects of increasing CO₂ and acidification are not universal. For example, primary producers such as phytoplankton, algae, and sea grasses are known to increase their production under elevated CO₂. Increasing photosynthesis increases O₂ production, which can potentially counteract growing acidity in surrounding seawater. Research is under way on the effects of ocean acidification on single species, but studies on how ocean acidity affects marine ecosystems and food webs are also needed. Moreover, along with the acidification of oceans, water temperatures are rising, potentially creating multiple stressors for organisms.

Estuaries are places where the dual effects of ocean acidification and temperature on primary producers and their food webs may be particularly relevant. Among the most productive ecosystems on Earth, estuaries support a diverse array of marine organisms, including commercially important fish species. Because estuaries are at the interface between land and sea, they have been highly affected by humans through intense overfishing, habitat destruction, and pollution from rivers. Estuaries also experience warm water temperatures, a condition that could intensify with global warming. But estuaries may also be places where the effects of ocean acidification could be mitigated if primary producers such as macroalgae and sea grasses are able to sequester CO₂ and provide more food and habitat for higher trophic levels.

Research on estuaries was conducted by a group of researchers on the western coast of Sweden. The group focused on a food web that includes algae primary producers and invertebrate consumers and exposed this food web to different conditions of CO₂ and temperature. What they found suggests that ocean acidification and temperature affect food webs in complex ways that may be hard to predict.

QA How will food webs respond to the multiple effects of ocean acidification and warming in marine ecosystems?

57.1 Ecosystem Science Considers How Energy and Nutrients Flow through Biotic and Abiotic Environments

In [Chapter 56](#) we looked at communities and the roles that species play in shaping their structure and function. In this chapter we will consider how energy flows and nutrients cycle through communities, a branch of ecology known as [ecosystem science](#).

ecosystem science A branch of ecology that considers how energy flows and nutrients cycle through communities.

focus your learning

Ecosystems include all the organisms in a given area and their physical and chemical environment.

Energy sources in ecosystems result from the processes of photosynthesis, chemosynthesis, and metabolism; energy is transferred via primary and secondary production.

Autotrophs and heterotrophs obtain required nutrients in different ways.

An [ecosystem](#) is all the organisms in a given area and the physical and chemical environment in which they live. The term was first coined by A. G. Tansley, a plant ecologist who was interested in how the flow of energy and chemicals was influenced by both the biotic and abiotic components of the environment.

ecosystem (eek' oh sis tum) The organisms of a particular community together with the physical and chemical environment in which they live.

Just like communities, ecosystems occupy a wide range of spatial scales, making them hard to delineate precisely (see [Key Concept 56.1](#)). For that reason, ecologists often define an ecosystem using subsets of species and components of the physical and chemical environment based on the questions they are investigating. For example, a soil ecosystem might include only the bacteria that transform nitrogen into forms plants can use. Or an estuarine ecosystem might be confined to the cycling of carbon through a food web of algae and their consumers, as you saw in the opening story.

Energy flowing through ecosystems originates with sunlight and inorganic and organic compounds

The flow of energy through ecosystems comes in a variety of forms (**Focus: Key Figure 57.1**). The most obvious source is the sun, which delivers radiant energy that warms Earth and provides energy for photosynthesis. Autotrophs such as plants, algae, and photosynthetic bacteria capture that radiant energy and fix it into organic compounds that make up the tissues of organisms (see [Figure 57.1A](#)). Energy can also come from the oxidation of inorganic nutrients

by archaea and bacteria through the process of **chemosynthesis**, which involves using energy from inorganic compounds to take up CO_2 and produce carbohydrates (see p. 545). Chemosynthesis typically occurs in ecosystems that lack sunlight and have high concentrations of particular inorganic compounds, such as hydrothermal vents, hot springs, and soils. These two forms of energy capture and carbon fixation are both involved in a process known as primary production. Ecologists use the term “primary productivity” to indicate the rate of primary production over time.

focus: key figure

Figure 57.1 Energy Flows and Chemical Nutrients Cycle through

Ecosystems**(A)**The flow of energy through ecosystems comes mostly from the sun, which delivers radiant energy for photosynthesis by primary producers. **(B)** Primary producers then provide energy to organisms at higher trophic levels in food webs, but some of that energy is lost as metabolic heat. **(C)** Nutrients continually cycle between living organisms and the physical components of ecosystems.

Q: Why does energy “flow” but nutrients “cycle” through ecosystems?

chemosynthesis The use of energy from inorganic chemical compounds by archaea and bacteria to fix CO₂ and produce carbohydrates using the Calvin cycle.

A third source of energy in an ecosystem is the product of primary production—the organic compounds synthesized through photosynthesis and chemosynthesis—that is made available for organisms at higher trophic levels in food webs (see [Figure 57.1B](#)). This source of energy, known as [secondary production](#), is contained within the tissues of organisms and is used to power the metabolism of heterotrophs, or the consumers within food webs, which include herbivores, carnivores, omnivores, parasites and pathogens, and eventually decomposers. Metabolism involves converting the organic compounds in food into useable energy—primarily ATP—by processes such as glycolysis (see [Key Concept 9.1](#)). The main by-products of metabolism are inorganic compounds, CO₂, and water. The energy generated by metabolism to support the “work” that organisms do in their daily life is eventually lost from the ecosystem in the form of metabolic heat.

secondary production Source of energy for organisms and ecosystems that is derived from the consumption of organic compounds produced by other organisms.

Nutrients cycling through ecosystems originate in soil, water, and the atmosphere

In contrast to energy, which is ultimately lost from an ecosystem as heat, nutrients continually cycle between living organisms and the abiotic components of ecosystems (see [Figure 57.1C](#)). Organisms require 30-40 different nutrients, including the macronutrients carbon, hydrogen, nitrogen, calcium, phosphorus, potassium, and magnesium, and micronutrients such as iron, manganese, zinc, and copper. All the chemical components in the bodies of organisms ultimately originate from soil, water, or the atmosphere, but organisms acquire these materials in many different ways. Autotrophs such as plants take up certain elements directly from soil, water, and the atmosphere and incorporate them in their tissues. Heterotrophs generally acquire elements by consuming the biomass of other organisms, and then reassemble them via chemical reactions. Some heterotrophs acquire some elements from mutualistic microbes that convert them into forms that are usable by their hosts.

Gas exchange by living organisms returns certain elements to the atmosphere as gases. After organisms die, the materials in their bodies become detritus and are broken down by decomposers into simpler biochemical components, which then can be used by autotrophs once again. Elements not used by autotrophs can accumulate in soil, water, or sediments.

An ecosystem is all the organisms in a given area and their physical and chemical environment. Autotrophs such as plants, algae, and photosynthetic bacteria capture sunlight and fix it into organic compounds (primary production). Energy is also derived through chemosynthesis: the oxidation of inorganic nutrients by archaea and bacteria. Energy captured through primary production is in turn available for organisms at higher trophic levels in food webs (secondary production). Nutrients continually cycle between living organisms and the abiotic environment.

learning outcomes

You should be able to:

- Compare different ways of defining an ecosystem, and contrast ecosystems with communities.
- List sources of energy in ecosystems, and associate each source with the processes that produce them.

-
1. An ecologist measures the number of species in an ecosystem. Is she conducting ecosystem science? Explain.
 2. Describe the two ways that energy and carbon are converted into primary production.

For the remainder of this chapter we will consider in more detail how energy flows and nutrients cycle through ecosystems as depicted in [Figure 57.1](#). We will start with primary production, where energy and nutrients are first captured in ecosystems.

57.2 Energy and Nutrients in Ecosystems Are First Captured by Primary Producers

The overwhelming majority of the primary production on Earth comes from photosynthesis. Plants, algae, and bacteria fix carbon by capturing energy from the sun (or inorganic nutrients, in the case of chemosynthesis) and using that energy to convert carbon dioxide into carbon compounds that can then be used by higher trophic levels.

focus your learning

Net primary production (NPP) varies by latitude and type of biome.

The FACE (free air CO₂ enrichment) experiment studied the response of plants to elevated atmospheric CO₂ concentrations.

Primary production in aquatic systems is limited by light (which is limited by depth) and by the availability of different nutrients, depending on the type of system.

Net primary production is the amount of carbon remaining in plants after respiration

Fixed carbon, be it from photosynthesis or chemosynthesis, is the currency used to measure primary production. The total amount of carbon fixed by primary producers in an ecosystem is called **gross primary production (GPP)**. Not all GPP becomes living plant matter, or biomass, because primary producers use some of that energy for their own respiration and other metabolic processes. Thus **net primary production (NPP)**, the amount of biomass incorporated into the tissues of primary producers after respiration, is the most common metric used to describe an ecosystem's carbon fixation. This relationship is represented mathematically as

gross primary production (GPP) The total amount of carbon fixed by primary producers in an ecosystem. (Compare with net primary production.)

net primary production (NPP) The amount of energy or biomass incorporated into the tissues of primary producers after respiration. (Compare with gross primary production.)

$$\text{NPP} = \text{GPP} - \text{respiration}$$

The carbon not used in respiration is then allocated to such important processes as growth, reproduction, and survival in the face of physical stress, herbivory, or diseases (see [Chapter 38](#)).

Patterns of primary production vary with latitude and ecosystem type

Largescale geographic variation in primary production is one of the most obvious ecological patterns on Earth. Only recently, however, have ecologists been able to reliably quantify patterns of productivity at global scales. Satellite-based optical sensing techniques now help scientists detect the amount of primary production on land and in the ocean at global scales. How do terrestrial and oceanic ecosystems compare, and how is NPP distributed across the

globe?

Estimates of global NPP show that the total amount of carbon taken up by terrestrial ecosystems (52%) is slightly higher than that taken up by the oceans (48%), even though oceans make up a greater percentage (70%) of Earth's surface. This difference arises because terrestrial ecosystems have a much higher per-area NPP ($426 \text{ g C/m}^2/\text{year}$) than do oceans ($140 \text{ g C/m}^2/\text{year}$).

Satellite imaging has also shown that NPP is distributed differently on land than in the ocean. NPP on land varies dramatically with latitude, whereas oceans show much less latitudinal variation (Figure 57.2). On land, NPP is highest in the tropics and declines at higher latitudes. Arid regions such as those in deserts (30° latitude) and at the poles (90° latitude) show extremely low NPP (Figure 57.3A). NPP rises slightly at mid-latitudes, especially in the Northern Hemisphere, where land area is larger than in the Southern Hemisphere (see Figure 57.2). In the oceans, NPP is highest at mid-latitudes and along coastal zones, especially those that experience upwelling (Figure 57.3B). NPP is also higher in the Southern Hemisphere, where ocean area is larger than in the Northern Hemisphere (see Figure 57.2).

Figure 57.2 Estimates of Total Oceanic, Terrestrial, and Global NPP by Latitude
On land, NPP is highest in the tropics and declines at higher latitudes. In the oceans, NPP does not vary much with latitude except at mid-latitudes, especially in the Southern Hemisphere. (1 petagram or Pg = 10^{15} g).

(A)

(B)

Figure 57.3 Geographic Variation in Terrestrial and Oceanic NPP Maps of NPP based on satellite sensor data. **(A)** Terrestrial NPP is highest in the tropics and lowest in arid regions and at the poles. Gray areas represent unvegetated land masses, including deserts and ice caps. **(B)** Oceanic NPP is highest at mid-latitudes and in coastal and upwelling zones.

Remote sensing has also revealed variation in NPP among different ecosystem types or biomes. Tropical rainforest ecosystems have the second-highest average and net NPP, even though they make up only a little over 3 percent of Earth's surface ([Figure 57.4](#)). In comparison, the open ocean ecosystems have a low average NPP, despite the large area over which they occur. Some marine ecosystems such as estuaries and algal beds and coral reefs have some of the highest average net primary productivity, but their small geographic areas make their

contributions to global NPP modest. It is important to note, however, that the primary producers in these ecosystems contribute substantially to local and regional NPP and thus are critical to marine food webs.

Figure 57.4 Ecosystems Differ in NPP The contribution of different ecosystem types to global NPP can be measured by **(A)** their geographic extent and **(B)** their average net primary productivity. **(C)** Combining these two measures gives the proportional contribution of each ecosystem type to Earth's total NPP

Not surprisingly, the patterns of primary production that we see on land versus ocean, and among ecosystem types, can be explained by separate factors that control primary production in terrestrial versus aquatic systems. we will now consider these factors in more detail—first on land, and then in oceans and lakes.

Rainfall and temperature largely control terrestrial primary production

The strong latitudinal patterns in terrestrial NPP reflect variation in global climate, particularly rainfall and temperature, across latitudes and seasons. NPP increases as average annual rainfall increases up to a maximum (approximately 240 cm per year), but then declines in most ecosystems ([Figure 57.5A](#)). The decrease in NPP with high rainfall can occur because of sunlight being reduced by cloud cover over long periods of time or as a consequence of nutrient loss or flooding. NPP also increases with average annual temperature([Figure 57.5B](#)). Thus it makes sense that close to the equator, where temperatures and rainfall are high throughout the year, conditions are ideal for primary producers. In deserts, even though temperatures can be high, plant growth is limited by a lack of rainfall. At higher latitudes or elevations, even though moisture is generally available, NPP is low because it is relatively cold much of the year and the growing season is shorter than at lower latitudes or elevations.

Figure 57.5 Global Patterns of Terrestrial NPP Correlate with Climate The plots show the relationships between NPP for different terrestrial ecosystems and (A) precipitation and (B) temperature of those ecosystems worldwide. (1 megagram or Mg = 10^6 g.)

In addition to being affected by global climate, terrestrial NPP is also affected by nutrient availability and atmospheric CO_2 concentrations. How these two factors affect primary production is of special interest given the increasing use of artificial fertilizers and rising atmospheric CO_2 concentrations from the burning of fossil fuels (see [Key Concept 57.4](#)). A looming question is whether plants, by taking up CO_2 , might be able to offset increasing CO_2 emissions. An ambitious experiment exploring this possibility was conducted in 1996. The FACE (*free—air* CO_2 enrichment) experiment involved artificially increasing CO_2 concentrations within arenas constructed around pine trees in North Carolina ([Figure 57.6A](#)). To test whether nutrients were a limiting factor, nitrogen was added to half the plots. By 2000, trees showed a slight increase in NPP (measured as woody tissue biomass) in the elevated CO_2 plots compared with the ambient plots ([Figure 57.6B](#)). The increase in NPP, however, was significant only in the fertilized plots, suggesting that nutrients are a limiting factor in the assimilation of CO_2 by plants. Since the initial FACE experiment, more than 12 similar large-scale experiments have been conducted in a variety of ecosystems, including grasslands and agricultural crops. The results generally confirm those found in North Carolina, but there are differences. Trees are generally more responsive than herbaceous species to elevated CO_2 concentrations, and grain crop yields increase far less than anticipated.

(A)

(B)

Figure 57.6 FACE Experiment: Effects of CO₂ and Nutrients on NPP (A) The free—air CO₂ enrichment (FACE) experiment involved releasing CO₂ from towers constructed around pine trees. (B) The trees grew better under conditions of elevated CO₂ (550 parts per million) and nutrients compared with ambient conditions. Without added nutrients, CO₂ had a minimal effect on tree growth.

The FACE experiments remind us that terrestrial ecosystems can vary widely in their NPP, as you saw in [Figure 57.4](#). Clearly some of this variability is a simple consequence of global and regional climate promoting the formation of certain types of ecosystems and biomes, as is illustrated by Walter climate diagrams. But the types of plant species present can also determine the NPP of an ecosystem. For a given set of environmental conditions, plant species can vary widely in their NPP depending on their photosynthetic pathway (e.g., [*C₃ versus C₄ plants](#), or trees versus shrubs versus grasses), which regulates their rate of photosynthesis. Moreover, nutrient limitation can play a major role in NPP in certain ecosystems. For example, in lowland tropical forests, NPP is often limited by phosphorus, calcium, and potassium. In temperate and arctic ecosystems, nitrogen and phosphorus can be limiting.

Light and nutrients combine to control aquatic primary production.

[Chapter 53](#) described how Earth's topography affects water depth, creating gradients in light, temperature, water pressure, and nutrient availability. The main primary producers in aquatic ecosystems—phytoplankton and algae—are most limited by light and nutrients along continental margins (coastal zones) and in the surface waters of oceans and lakes (photic zones) (see [Figure 53.9C and D](#)). Oceanic NPP peaks at mid-latitudes and along the continental margins (see [Figure 57.3B](#)) because these are regions where nutrient concentrations from ocean upwelling are high. Higher NPP is associated with estuaries as well, where nutrients can be "outwelled" from watershed runoff to coastal zones.

In aquatic systems, NPP is limited primarily by iron, nitrogen, and phosphorus. The relative importance of these three nutrients varies depending on the aquatic ecosystem. In much of the

open ocean, NPP is limited primarily by nitrogen. But in some locations, particularly the equatorial Pacific Ocean where excess nitrogen has been detected in surface waters, NPP by phytoplankton may be more limited by iron. In a series of experiments in the mid—1990s, biological oceanographers added iron sulfite to the surface waters off the Galapagos Islands and in the Southern Ocean to test the hypothesis that oceanic NPP, and thus the potential of the ocean to take up CO₂ and combat global warming and ocean acidification (see p.1239), was limited primarily by iron. The experiments showed that NPP was as much as four—to tenfold higher in the plume of water that received the iron additions. While the experiments show that iron limitation is a major factor in reducing the ability of the ocean to absorb CO₂ from the atmosphere, large-scale fertilization of the oceans is impractical at best, and may be somewhat counteracted by respiration of CO₂ by zooplankton and bacteria feeding on phytoplankton.

In lake ecosystems, NPP is limited primarily by phosphorus. The effect of phosphorus on lake NPP was first studied in connection with the declining water quality of lakes in North America and Europe. Wastewater and sewage were implicated in a dramatic increase in [eutrophication](#), a process of ecosystem change initiated by an increase in nutrients consumed by phytoplankton, cyanobacteria, and algae in aquatic systems. Eutrophication can result in the explosive growth of algae (algal blooms). Decomposition of large volumes of dead algae by bacteria can in turn severely deplete oxygen needed by aquatic life (hypoxia). To understand which nutrients were most important to the blooms, David Schindler and colleagues conducted whole lake fertilization experiments, starting in 1969, in a set of small lakes in Ontario, Canada. They added nitrogen, carbon, and phosphorus to all or half of several lakes and found that phosphorus was the major trigger for phytoplankton and cyanobacteria blooms ([Figure 57.7](#)). These experiments set in motion a campaign to reduce phosphorus in wastewater by recommending the banning of phosphates in detergents and stripping them chemically in sewage treatment plants.

eutrophication (yoo trofe' ik ay' shun) [Gk. *eu*: truly + *trephein*: to flourish] A process in aquatic ecosystems initiated by a pulse of nutrients that results in an increase of algal growth that may lead to decomposition and depleted oxygen conditions (hypoxia).

Figure 57.7 Lake NPP Responds to Phosphorus Fertilization Experiments show that the addition of phosphorus to a lake causes massive phytoplankton and cyanobacteria blooms.

57.2 recap

Fixed carbon, be it from photosynthesis or chemosynthesis, is used to measure primary production. Net primary production is the amount of biomass incorporated into the tissues of primary producers after respiration, and it varies with latitude and ecosystem type. On land, NPP is highest in the tropics where temperatures are high year-round and rainfall is abundant. In the oceans, NPP peaks along continental margins and in areas of upwelling, where the main primary producers-phytoplankton and algae-have access to light and nutrients. Nutrient runoff from agriculture and wastewater can cause eutrophication in aquatic systems, resulting in algal blooms and deadly low oxygen conditions (hypoxia).

learning outcomes

You should be able to:

- Analyze, with examples, the variation in NPP by latitude and biome in terrestrial and ocean ecosystems.

- Describe the FACE experiment and evaluate, with examples, how results of such experiments might shed light on the relationship between atmospheric CO₂ concentrations and plant production.
 - Describe the process, causes, and effects of eutrophication in aquatic ecosystems, and compare the importance of various nutrients in this process.
-

1. Consider [Figure 57.4](#). How does the average net primary productivity differ between the open ocean and algal beds and coral reefs? Why, then, is the percent of Earth's NPP so much higher for the open ocean?
2. Atmospheric CO₂ concentrations are rising at unprecedented rates. Is it reasonable to assume that primary producers on land and in the oceans will be able to appreciably lower global CO₂ concentrations? What evidence is there to support your answer?
3. Describe the process of eutrophication and name the nutrient most responsible for this process in lake systems.

Once the energy captured by primary producers is fixed as NPP, consumption by heterotrophs transfers a fraction of that energy to higher trophic levels. Next we will consider in more detail the factors important to the movement and loss of energy between trophic levels.

***connect the concept** As discussed in [Key Concept 10.4](#), C₃ and C₄ plants differ in how they fix CO₂ and can be distinguished according to whether the first product of CO₂ fixation is a three- or four-carbon molecule. See [Figure 10.16](#).

57.3 Food Webs Transfer Energy and Nutrients from Primary Producers to Consumers

You know from [Chapter 56](#) that food webs can be constructed to represent the interactions and energy transfer that occur between different species and trophic levels. For example, the food web presented in [Figure 56.3](#) shows the connections among primary producers and consumers in Yellowstone National Park. While the arrows indicate the trophic connections among species, they do not show how much energy is actually being transferred up the food web and converted into secondary production. We will now consider the factors important to secondary production.

focus your learning

Production efficiency varies based on whether the consumer is an ectotherm or an endotherm, and on the quantity and quality of food available.

Trophic efficiency varies among trophic levels and among ecosystems.

Omnivory and the number of trophic levels affect the transfer of energy through food webs.

Several factors may limit the number of trophic levels in a food web.

You know from [Key Concept 8.1](#) that during energy transfer, some energy is lost as “unusable” to the system (second law of thermodynamics) and thus is unavailable to do work. For food webs, the consequence of this loss is that only part of the primary production consumed by heterotrophs is converted into heterotroph biomass. What factors are important to this movement and loss of energy from primary to secondary production? [Net secondary production](#), or the amount of biomass obtained from the consumption of other organisms, depends on how much plant tissue is consumed ([consumption efficiency](#)), how much of the consumed food can actually be digested versus released as feces and urine ([assimilation efficiency](#)), and how much of the digested food is used in metabolic activities and released as CO₂ through respiration versus stored as biomass ([production efficiency](#)) ([Figure 57.8](#)). We can think of production efficiency as the percentage of energy stored in assimilated food that is used to produce new biomass.

net secondary production The amount of energy or biomass obtained from the consumption and assimilation of other organisms, taking into account respiration.

consumption efficiency The proportion of available biomass that is ingested by consumers.

assimilation efficiency The proportion of ingested biomass that consumers assimilate by digestion.

production efficiency The proportion of assimilated biomass used to produce new consumer biomass or net secondary production.

Figure 57.8 Energy Flow and Net Secondary Production in an Herbivore The proportion of energy transferred between a caterpillar and its plant food depends on efficiencies of consumption, assimilation, and production.

Q: Why do you think herbivores have lower production efficiencies than carnivores?

Consumers can vary dramatically in production efficiency. For example, endotherms have much lower production efficiencies than ectotherms ([Table 57.1](#)). Because endotherms have to maintain high body temperatures, they have higher metabolic rates than ectotherms, and thus have less energy left over to devote to growth and reproduction. Moreover, endotherms vary in production efficiency depending on body size and metabolism. Larger mammals have lower metabolic rates and higher production efficiencies compared with smaller mammals and birds, whose greater surface area-to-biomass ratios result in more heat loss and higher metabolic rates (see [Key Concept 39.5](#)).

table 57.1 Production Efficiencies of Consumers

Consumer group	Production efficiency (%)
Endotherms	
Birds	1.3
Small mammals	1.5
Large mammals	3.1
Ectotherms	
Fishes and social insects	9.8
Nonsocial insects	40.7
Herbivores	38.8
Detritivores	47.0
Carnivores	55.6
Non-insect invertebrates	25.0
Herbivores	20.9
Detritivores	36.2
Carnivores	27.6

Source: Data from Humphreys 1979.

Because production efficiency affects the growth and reproduction of consumers, changes in

the quality and quantity of food can lead to population declines. Research on Steller sea lions in the Gulf of Alaska and the Aleutian Islands offers a case in point. Sea lion populations declined by 85 percent over a 25-year period starting in the early 1970s. Surveys of sea lion individuals showed that they were smaller and had lower birth rates compared with individuals before the decline, suggesting that food was a limiting factor. Prior to the decline, sea lions mostly fed on herring, rich in fats, along with lesser amounts of cod and pollock. But when herring populations declined in the 1970s, the sea lion diet consisted mostly of cod and pollock. The energy per gram of biomass of pollock and cod is roughly half that of herring, so sea lions would have needed to eat twice as much pollock and herring to make up for the loss in herring calories. While plenty of fish were available, consumption of a greater percentage of inferior food represented a decline in production efficiency, which in turn translated into a decline in sea lion populations.

The amount of energy transferred within food webs depends on trophic efficiency

In addition to understanding how energy flows between individual consumers, we can also consider how it flows between trophic levels. **Trophic efficiency** is a measure of the amount of energy at one trophic level divided by the amount of energy at the trophic level immediately below it. Trophic efficiency varies among ecosystems as well as trophic levels. Pyramid diagrams such as those in [Figure 57.9](#) illustrate the proportions of energy transferred from each trophic level to the next, making it possible to compare energy flow in different ecosystems. Pyramid diagrams can also be used to illustrate the amount of biomass found at each trophic level. As seen in [Figure 57.9A](#) and [B](#), terrestrial ecosystems progressively lose energy from one trophic level to the next through trophic inefficiencies, especially between the primary producer and primary consumer levels. Note also that terrestrial ecosystems support less biomass at higher trophic levels than at lower trophic levels. Forest ecosystems have lower trophic efficiency than grasslands because much of the biomass in forests is in the form of wood, most of which is unavailable to primary consumers.

trophic efficiency A measure of the amount of energy or biomass at one trophic level divided by the amount of energy at the trophic level immediately below it.

Figure 57.9 Pyramid Diagrams Show Energy Flow and Biomass in Food Webs

Pyramid diagrams allow ecologists to compare patterns of energy flow and biomass in food webs. **(A)** Forest eco-systems have lower trophic efficiency than **(B)** grasslands because much of the biomass in forests is wood, and thus unavailable to most primary consumers. **(C)** In open oceans, the rapid rate of primary production can support a larger biomass of primary consumers.

In aquatic systems, trophic efficiencies are much higher. Here pyramid diagrams also show a progressive loss of energy at higher trophic levels, as in terrestrial systems, but the corresponding biomass pyramids are inverted (see [Figure 57.9C](#)). Why might this be? The phytoplankton that are the primary producers in aquatic ecosystems grow and reproduce much more rapidly than do the zooplankton and small fishes that consume them, so their smaller biomass, with its rapid rate of primary production, can actually support a larger biomass of primary consumers. In part, this difference between terrestrial and aquatic systems explains why land is green but oceans are blue. Terrestrial ecosystems have primary production that far exceeds rates of herbivory, while the opposite is true for large portions of the ocean. Overall, estimates suggest that, on average, only 13 percent of terrestrial biomass is consumed by primary consumers, compared with 35 percent in aquatic ecosystems.

Food webs are controlled by bottom-up and top-down forces

The control of energy flow in an ecosystem occurs in two ways. First, as discussed in [Key Concept 57.2](#), the amount of energy entering a food web can depend on the NPP of that system, which depends on such factors as rainfall, temperature, light, and nutrients. The more

NPP entering the system, the more energy that is passed up the food web to consumers. This flow of energy is referred to as “bottom-up” control because it comes from the “bottom,” or primary producer trophic level ([Figure 57.10A](#)). The other type of control on energy flow can come from consumers at higher trophic levels, who regulate the amount of NPP by feeding on lower trophic levels. This control is referred to as “top-down” control because it comes from the “top,” or the secondary consumer trophic level.

Figure 57.10 Bottom-up and Top-down Control of Food Webs (A) Production in an ecosystem can be viewed as mostly being controlled by limiting resources (bottom-up) or by consumers at higher trophic levels (top-down). (B) A three-level food web, in which the secondary consumer affects the primary consumer’s abundance, has higher NPP (represented by the size of the green circle) than a two- or four-level food web. (C) A three-level food web with omnivory has lower NPP than a food web without omnivory.

All food webs are controlled by both bottom-up and top-down pathways, but the relative importance of that control can vary depending on the food web in question. For example, food webs that experience a trophic cascade driven by a keystone predator, as you saw in the examples of wolves in Yellowstone National Park (see [Figure 56.9](#)) and sea otters in kelp forests, are dominated by top-down control (see [Key Concept 56.3](#)). In those two cases, it was the top predator that controlled the prevalence of primary producers (aspens and kelp, respectively), rather than limiting resources per se.

There are also clear examples of bottom-up control in food webs. For example, in a study of pelagic ecosystems off the coast of western North America, researchers found a strong positive correlation between phytoplankton abundance, zooplankton abundance, and fish production (measured from fisheries-catch data). Phytoplankton abundance in this region is largely controlled by ocean upwelling, which brings nutrients to the light-saturated surface waters for use by phytoplankton. The intensity of upwelling varies along the coast, thus creating “hot spots” of productivity that are reflected in the fish populations of the region.

The number of trophic levels can control the flow of energy through food webs

You know from the previous section that changes in the abundance of organisms at one trophic level can influence the energy flow at multiple trophic levels. You might imagine that the number

of trophic levels in a food web could be important in the magnitude of that influence. Indeed, all things being equal, a three-level food web, in which the secondary consumer affects the primary consumer's abundance, should have higher NPP than a two- or four-level food web in which primary consumers have less secondary consumer control ([Figure 57.10B](#)). Omnivory, or feeding on more than one trophic level, can also change the way energy is transferred in food webs by essentially "collapsing" trophic levels on one another. For example, a three-level food web with a secondary consumer feeding on both the primary consumer and primary producer should have lower NPP than a three-level food web without omnivory ([Figure 57.10C](#)). That's because even though the secondary consumer indirectly benefits the primary producer by feeding at the primary consumer level, it partially negates this effect by directly feeding on the primary producer as well.

While the number of trophic levels in food webs can vary, most food webs have three or four trophic levels, with the rare exception of five or more in some systems. What factors might be important in limiting the number of trophic levels in food webs? Several factors have been hypothesized to be important:

The amount of NPP entering the system: This hypothesis suggests that bottom-up factors can influence trophic structure. Given that a large amount of energy is lost from one trophic level to the next (see [Figure 57.9](#)), the number of trophic levels will be limited by the amount of energy that can sustain populations at higher trophic levels.

The amount of disturbance: This hypothesis suggests that longer food webs are less likely to recover from disturbances than shorter food webs, which can presumably reassemble more quickly given the fewer trophic levels, and species, involved.

The evolutionary constraints on top predators: This hypothesis focuses on the idea that no organisms on Earth today, with the exception of humans, have evolved to capture apex predators such as birds of prey, sharks, killer whales, and polar bears. With evolutionary constraints maintaining top predators at the pinnacle of food webs, the number of higher trophic levels is limited.

57.3 recap

Once energy captured by primary producers is fixed as NPP, consumption by heterotrophs transfers a fraction of that energy to higher trophic levels (net secondary production). Terrestrial systems have lower trophic efficiencies than aquatic systems, where the rapid rate of primary production supports greater secondary production. The flow of energy in food webs is influenced by the number of trophic levels and the relative contribution of bottom-up and top-down forces. Food webs are typically restricted to three or four trophic levels because of energy limitations at higher trophic levels, the effects of disturbance, and/or evolutionary constraints on top predators.

learning outcomes

You should be able to:

- Compare and contrast, with examples, the production efficiencies of ectotherms and endotherms.
- Analyze why trophic efficiencies are higher in aquatic than in terrestrial ecosystems, and explain how this affects biomass throughout the food web.
- Analyze, both qualitatively and quantitatively, the effect that length of a food chain has on NPP in an ecosystem.
- Explain how omnivory can change the transfer of energy in a food web.

- Provide and explain hypotheses relating to control of the length of food chains.
-

1. Suppose there are two food webs, one in a forest, the other in a lake. All else being equal, which food web would have the higher trophic efficiency, and why? Comparing different species, which would have the higher production efficiency, a bear or a crayfish? Explain your answer.
2. Now compare two food webs in different lakes. One has three trophic levels, and the other has four. All else being equal, which would have the higher NPP? Why? If you added omnivory to the top level of the food web with four trophic levels, how would it differ in NPP compared with the food web without omnivory?
3. Compare a tropical rainforest food web that has five trophic levels with a food web in a desert having three trophic levels. What hypothesis might best explain the difference in trophic level length between the two ecosystems?

We've considered how energy flows from primary producers to consumers, and the implications of that flow for food webs. Besides energy, a key component of the metabolism and growth of organisms is nutrients (including water). Earlier in the chapter you read that nutrients continually cycle between living organisms and the abiotic environment via nutrient cycling (see [Figure 57.1C](#)). We will consider nutrient cycling next.

57.4 Nutrient Cycling in Ecosystems Involves Chemical and Biological Transformations

All nutrients that make up the tissues of organisms originate from either soil, water, or the atmosphere, and then cycle between organisms and their environment through (1) primary and secondary production and (2) decomposition ([Figure 57.11](#)). We considered production in the last two sections, but not decomposition. Decomposition occurs when detritus, or dead organisms and their waste products, are broken down by bacteria and fungi into energy and nutrients. Decomposition releases nutrients in a soluble form that can then be taken up by primary producers and microorganisms. Detritus can come in many forms, including plants and animals, but is mostly made up of plant or algal matter. Detritus must first be broken down into smaller fragments by detritivores such as worms and arthropods before it can undergo mineralization (see [Figure 57.11](#)). **Mineralization** is the process by which animals, bacteria, and fungi convert organic compounds into inorganic soluble nutrients. Along the way, some of the nutrients may be lost to the system as gas to the atmosphere or minerals to ground water. The nutrient cycle is complete when the inorganic soluble nutrients produced through mineralization are used once again by primary producers or bacteria.

Figure 57.11 Nutrient Cycles A generalized nutrient cycle, showing the movement of nutrients among biotic and abiotic compartments of an ecosystem and the potential pathways for inputs and losses.

mineralization The process by which animals, bacteria, and fungi convert organic compounds into inorganic soluble nutrients.

focus your learning

Decomposition and mineralization are necessary to complete nutrient cycling in ecosystems. The average residence time of water molecules in the various pools of the hydrologic cycle

ranges from one week to thousands of years.

Fossil-fuel burning by humans is affecting Earth's carbon cycle, changing its climate and oceans.

Nitrogen, an abundant gas in Earth's atmosphere, is cycled primarily by microbial activity.

Most phosphorus is stored in rocks and deep-sea sediments, but it cycles rapidly through organisms and often limits plant growth.

Most sulfur is pooled in rocks and ocean sediments, but cycling produces different compounds on land and in oceans.

The movement of nutrients through food webs from uptake to decomposition—that is, through the biotic components of ecosystems—occurs primarily on a local scale. In contrast, abiotic processes can move nutrients far beyond the boundaries of the local ecosystem. Each of the chemical elements that organisms use in large quantities cycles in a distinctive way through the globe. Because geological, chemical, and biological processes are all important in moving materials around the planet, the pattern of movement of an element is called its **biogeochemical cycle**. The cycles are considered in terms of pools—the amount of elements within certain parts of the abiotic and biotic environment—and fluxes, or the rates of movement between pools. We will consider the biogeochemical cycling of water, carbon, nitrogen, phosphorus, and sulfur at the global scale because of their functional role in biological systems and their roles as pollutants in the environment.

biogeochemical cycle Movement of inorganic elements such as water, nitrogen, phosphorus, and carbon through living organisms and the physical environment.

Water cycles rapidly around the globe

We start our discussion of global biogeochemical cycles with the water cycle—known as the **hydrologic cycle**—not only because water serves as an essential element for organisms but because it plays an important role in transporting nutrients between compartments (**Figure 57.12**). Energy from the sun drives the hydrologic cycle by evaporating water from the vast surfaces of the oceans. Most of the water is returned to the oceans as rainfall, but a smaller fraction is transported over land. Ocean water vapor combines with terrestrial water vapor from soils, lakes and rivers, and plants as a consequence of ***evapotranspiration**, and falls as precipitation over land. Terrestrial precipitation eventually returns to the oceans via streams, coastal runoff, and groundwater flows. More than half of this volume of water is carried back to the oceans by Earth's four largest rivers: the Amazon in South America, the Nile in Africa, the Mississippi in North America, and the Yangtze in Asia.

hydrologic cycle The movement of water from the oceans to the atmosphere, to the soil, rivers, and lakes, and back to the oceans.

Figure 57.12 The Global Hydrologic Cycle Water is essential for life on Earth. The estimated pools in major compartments (white boxes) and the annual fluxes between compartments (arrows) are expressed in units of 10^{18} grams.

Animation 57.1 The Global Hydrologic Cycle www.Life11e.com/a57.1

Despite their relatively small volume, rivers play a disproportionate role in the hydrologic cycle because the average residence time of a water molecule in rivers is only a few years. By comparison, the average residence time of a water molecule in lakes ranges from a few years to centuries. The larger the lake, the longer the residence time; the residence time for water in the top portion of Lake Superior, for example, is 1,500-2,000 years, and the water at the bottom of this massive lake cycles over much longer time scales. In the oceans the average residence time of a water molecule is about 3,000 years. Other pools of water include glaciers (with residence times of 20-100 years), seasonal snow cover (a few months), and soil moisture (1-2 months). The average residence time of water in the bodies of organisms is particularly brief, averaging just under a week.

Although large amounts of groundwater are present in underground pools called **aquifers**, this water has a long residence time underground and plays only a small role in the hydrologic cycle. In some places, however, aquifers are being depleted because humans are using groundwater more rapidly than it can be replaced, primarily for irrigation. On the North China Plain, depletion of shallow aquifers is forcing people to sink wells more than 1,000 meters deep to reach groundwater. If current water consumption patterns continue, it has been estimated that by 2025 at least 48 percent of the current world population will live in areas with inadequate water supplies.

aquifer A large pool of groundwater.

The carbon cycle is being altered by human activities, resulting in climate change

All of the important macromolecules that make up living organisms contain carbon, and much of the energy that organisms use to fuel their metabolic activities is stored in carbon-containing (organic) compounds. On land, biological processes move carbon directly between organisms and the atmosphere as terrestrial organisms take up carbon during photosynthesis and return it to the atmosphere through respiration and metabolism ([Figure 57.13](#)). In contrast, carbon dioxide moves into ocean waters from the atmosphere primarily by simple diffusion at the ocean surface; this dissolved CO_2 is the source of the carbon used by marine primary producers. Even taken together, however, the amounts of carbon in the atmosphere, in soils, and in living and dead organisms are dwarfed by the vast quantities of carbon stored in terrestrial rocks, in fossil fuels, in marine sediments, and in seawater in the form of carbonate ions (CO_3^{2-}) or bicarbonate ions (HCO_3^-) (see [Figure 57.13](#)).

Figure 57.13 The Global Carbon Cycle Carbon is the basis of the organic molecules and energy essential for life. The estimated pools in major compartments (white boxes) and the annual fluxes between compartments (arrows) are expressed in units of 10^{18} grams.

Animation 57.2 The Global Carbon Cycle www.Life11e.com/a57.2

Over the span of life's existence on Earth, quantities of carbon were removed from active cycling when organisms died in large numbers and were buried in sediments lacking oxygen. In such anaerobic environments, with few detritivores to reduce organic carbon to CO₂, organic molecules accumulate and are eventually transformed into deposits of oil, natural gas, coal, or peat—the **fossil fuels** that modern humans use as a combustible source of energy. Humans have discovered and used these fossil fuels at ever-increasing rates during the past 150 years. As a result, CO₂, one of the final products of burning fossil fuels, is being released into the atmosphere faster than it is absorbed in the oceans or incorporated into terrestrial biomass. Measurements of CO₂ on the top of Mauna Loa, Hawaii, show that, even though atmospheric CO₂ varies seasonally because of the change in NPP, it has steadily increased over the last 55 years of data collection (**Figure 57.14**).

fossil fuels Fuels, including oil, natural gas, coal, and peat, formed over geologic time from organic material buried in anaerobic sediments.

Figure 57.14 Atmospheric CO₂ Concentrations Are Increasing Carbon dioxide concentrations have been recorded since 1960 on top of Mauna Loa, Hawaii, far from most sources of human-generated CO₂ emissions. Although concentration vary seasonally, the trend has been consistently upward.

ATMOSPHERIC CO₂ AND GLOBAL CLIMATE CHANGE

Carbon dioxide is a greenhouse gas, so we would expect increasing atmospheric CO₂ concentrations to trap more heat in Earth's atmosphere and raise temperatures at Earth's surface (see **Figure 53.2**). What evidence do we have that this is occurring? Measurements of gases in air trapped in the Antarctic and Greenland ice caps show that temperatures have been warmer when atmospheric CO₂ concentrations have been higher and cooler when they have been lower (**Figure 57.15**). For example, the atmospheric CO₂ concentration was very low at the end of the last glaciation (180 parts per million [ppm]), 18,000 years ago, when temperatures were much colder than they are today. In contrast, during a warm interval between 11,000 years ago and the start of the Industrial Revolution (1750), the concentration of CO₂ in Earth's

atmosphere was between 260 and 280 ppm. Today atmospheric CO₂ concentration is just over 400 ppm (see [Figure 57.14](#)), the highest recorded in the last 800,000 years. The increase in CO₂ (and two other greenhouse gases, CH₄ and N₂O) from the burning of fossil fuels has resulted in a roughly 1 °C (1.8 °F) rise in global temperatures compared with those from 1981 to 2010 (a comparison known as a “temperature anomaly”).

Figure 57.15 Higher Atmospheric CO₂ Concentrations Correlate with Warmer Temperatures Atmospheric concentrations of CO₂ (measured in air bubbles trapped in Antarctic ice) have varied with temperatures over Antarctica (estimated with oxygen isotope analysis) for more than 800,000 years. “Temperature anomaly” is the change in Antarctic temperatures compared to modern temperatures.

How global climates and ecosystems will change in response to this rapid warming is a subject of intense investigation. Global warming has already resulted in the shrinking of Arctic sea ice, which is currently the lowest ever recorded. As temperatures continue to rise and glacial ice melts, sea level rises (because of both thermal expansion of ocean waters and the addition of glacial meltwater), increasing flooding of coastal cities and agricultural lands, especially during extreme storm events. Nearly one-third of the world’s population lives in coastal regions, which make up only 4 percent of Earth’s total land area.

Even though atmospheric CO₂ is increasing as the result of burning fossil fuels, less than half of the CO₂ released into the atmosphere by human activities remains in the atmosphere. Where does the rest of the CO₂ wind up? Much of it is absorbed by the oceans in inorganic forms. Over decades to centuries, the oceans exert a large influence over atmospheric CO₂ concentrations. Of the CO₂ absorbed by the ocean, some is used in photosynthesis by phytoplankton in the surface waters. These organisms remove dissolved CO₂ from water, thereby increasing the rate at which atmospheric CO₂ is absorbed by surface waters, but as you saw earlier, there are limits to this absorption given nutrient limitation in vast parts of the open ocean. In addition, many marine organisms (including clams, oysters, corals, and planktonic foraminiferans) incorporate carbon in their shells and other structures in the form of calcium carbonate (CaCO₃), which is synthesized by combining bicarbonate ions (HCO₃⁻) and calcium ions (Ca²⁺) dissolved in seawater. When these organisms die, those shells and their embedded carbon sink to the ocean floor.

Today’s oceans absorb millions of tons of CO₂ from the atmosphere each day—more than at any time during the past 20 million years. As a result, water near the ocean surface is becoming more acidic. As CO₂ concentrations in the atmosphere rise, more of the gas diffuses into the water at the ocean surface, where it reacts with water to form carbonic acid (H₂CO₃). As levels of carbonic acid rise, the pH of seawater drops. This increase in acidity can have negative effects on many marine organisms, particularly corals. The combination of decreasing pH and increasing water temperature to which corals are being exposed results in *** coral bleaching** and sometimes the death of corals. Because so many other reef species depend on corals and the structure they provide, an entire reef community can collapse if its corals fail to thrive.

But as you read in the opening story, the effects of CO₂ and ocean acidification vary depending on the organisms or ecosystems considered. [Investigating Life: Food Webs in an Acidic and Warming Ocean](#) describes research in Sweden by marine ecologists interested in the effects of ocean acidification and warming on an ecologically critical but predominately primary-producer-dominated ecosystem: estuaries. In this system, the researchers focused on benthic microalgae, an important food source for a diversity of sediment-dwelling herbivores, including crustaceans, snails, and worms. Benthic microalgae indirectly benefit from higher trophic levels, particularly omnivores that feed on macroalgae competitors and herbivores of the microalgae. Using experiments the researchers discovered that the biomass of benthic microalgae did not appreciably change under the elevated CO₂ and warming manipulations. As it turned out, the consumers mediated the effects of ocean acidification and warming on benthic microalgae, suggesting that consumers, or other strongly interacting species in food webs, have the potential to modulate the effects of climate change in complicated and unpredictable ways.

Food Webs in an Acidic and Warming Ocean

experiment

Original Apr: Alsterberg, C., J. S. Eklöf, L. Gamfeldt, J. N. Havenhand and K. Sundbäck. 2013. Consumers mediate the effects of experimental ocean acidification and warming on primary producers. *Proceedings of the National Academy of Sciences USA* 110: 8603–8608.

Christian Alsterberg and his colleagues considered how the food web in an estuarine ecosystem on the western coast of Sweden was influenced by ocean acidification and warming. The researchers chose to focus on benthic microalgae (single-celled algae) and its interactions

with macroalgae and consumers. In this system, omnivores (i.e., a guild of medium-sized crustaceans and snails that feed on two trophic levels) affect the productivity of benthic microalgae in two ways: (1) they increase the light available to microalgae by feeding on macroalgae, and (2) they prey on herbivores of microalgae (i.e., a guild of small crustaceans, snails, and worms). To estimate the importance of ocean acidification and increased warming in a multi-species food web, the researchers conducted an experiment on the estuarine community in which CO_2 , temperature, and omnivores were manipulated.

HYPOTHESIS Increasing CO_2 and temperature will increase the biomass of macroalgae competitors, causing a decline in the biomass of benthic microalgae.

METHOD

1. Fill 30-liter buckets with seawater and add microalgae, macroalgae, and herbivores.
2. Apply three treatments:
 - a. two levels of seawater temperature (ambient and increased)
 - b. two levels of CO_2 (ambient and increased)
 - c. two levels of omnivores (present and absent)
3. At the end of a 5-week period over the summer, measure the biomass of benthic microalgae (as Chl *a* concentrations), macroalgae, and herbivores.

RESULTS

To simplify, the results from the following treatments are presented: ambient CO_2 and temperature and increased CO_2 and temperature, each with and without omnivores.

The researchers found that benthic microalgae biomass did not change under increased CO_2 and temperature. This was true regardless of whether omnivores were present. However, the removal of omnivores did cause a decline in benthic microalgae under ambient conditions, as would be predicted from the food web shown above.

Omnivore removal caused an increase in the biomass of macroalgae competitors and herbivores, which then led to a decline in benthic microalgae. Interestingly, even though there was no effect of increased CO_2 and temperature on microalgae biomass, the results showed that both macroalgae and herbivores increased in biomass under these conditions compared with ambient conditions. This was especially the case when omnivores were removed.

Herbivores

□ Ambient CO_2 and temperature
▨ Increased CO_2 and temperature

CONCLUSION What can you conclude about the effects of increased CO_2 and temperature on benthic microalgae in this estuarine food web? Explore this question in the following work with the data.

investigatinglife work with the data follows on next page.

work with the data

To interpret the Alsterberg et al. study, we consider why benthic microalgae biomass did not change under increased CO_2 and temperature within the context of the experimental manipulation of the food web.

QUESTIONS►

1. Draw two food webs for this system, one with and one without the omnivores. Use arrows to indicate the direct (solid) and indirect (dashed) interactions and symbols to indicate negative (–) or positive (+) interactions.
2. Now, using data from the graphs in the experiment, modify the two food webs to show how increased CO_2 and temperature will affect the strength and direction of the food web interactions. Vary the width of the arrows to indicate the relative strength of the interactions, and use symbols to indicate whether the interactions are negative (–) or positive (+). Indicate whether benthic microalgae increase, decrease, or stay the same compared with ambient conditions.
3. Using the food webs you drew for the answer to Question 2 as your guide, explain why increased CO_2 and temperature had no effect on microalgae biomass compared with the ambient conditions.
4. Under increased CO_2 and temperature, what would happen to benthic microalgae biomass if the omnivores ceased feeding on macroalgae and just preyed on herbivores?

A similar **work with the data** exercise may be assigned in **LaunchPad**.

In terrestrial ecosystems, photosynthesis, principally in tropical forests, typically absorbs about the same amount of carbon that is released by terrestrial plants, microbes, and animals through metabolism. In more recent times, as atmospheric CO_2 increases, the photosynthetic consumption of CO_2 exceeds its metabolic production, which means Earth's terrestrial vegetation is storing carbon that would otherwise be increasing atmospheric CO_2 concentrations—but as we saw in the FACE experiment, we cannot count on terrestrial vegetation to store the vast amounts of excess CO_2 that human activities produce. Furthermore, climate warming (another result of increasing atmospheric CO_2 concentrations, as you have already seen) increases plant metabolism and is thus likely to increase the flux of CO_2 from vegetation into the atmosphere.

The nitrogen cycle is dominated by biotic processes

Nitrogen gas is the most abundant gas in Earth's atmosphere, but most organisms cannot use nitrogen in its gaseous form. Nitrogen enters the system as atmospheric N_2 and is fixed by bacteria into ammonia (NH_3) ([Figure 57.16](#)). Ammonia is rapidly transformed into ammonium (NH_4^+), which can then be used by plants and bacteria. Nitrifying bacteria can transform ammonium to nitrite (NO_2^-) and then nitrate (NO_3^-), both forms of nitrogen that plants and

bacteria can use. Denitrifying bacteria take nitrate and convert it back to N_2 and N_2O gases, which are then released back into the atmosphere. Along the way, plants and bacteria incorporate the nitrogen into their tissues, making it available to higher trophic levels as secondary production and eventually to decomposers. Collectively this microbial processing of nitrogen accounts for about 95 percent of all natural nitrogen flux on Earth, making it a mostly biologically driven cycle ([Figure 57.17](#)).

Figure 57.16 The Nitrogen Cycle Nitrogen fixation, nitrification, nitrate reduction, and denitrification are components of an essential chemical cycle that converts atmospheric nitrogen gas into ammonium ions and nitrate ions—forms of nitrogen that can be taken up by plants—and returns N_2 to the atmosphere.

Figure 57.17 The Global Nitrogen Cycle The largest pool of nitrogen is in the atmosphere in the form of nitrogen gas, N_2 . Nitrogen cycles through the biosphere primarily via the processes of nitrogen fixation, which converts inorganic nitrogen to an organic form usable by plants, and denitrification, which returns N_2 to the atmosphere. The estimated pools in major compartments (white boxes) and the annual fluxes between compartments (arrows) are expressed in units of 10^{12} grams.

Q: How does the industrial fixation of nitrogen (as a percentage) compare with the other forms of fixation on land?

Animation 57.3 The Global Nitrogen Cycle www.Life11e.com/a57.3

All living organisms require nitrogen, and the inability of the vast majority of organisms to use N_2 means that usable nitrogen is often in short supply. Populations of nitrogen-fixing organisms rarely increase in abundance to the extent that nitrogen is no longer limiting, because the end products of their nitrogen fixation are rapidly lost from ecosystems (ammonia by vaporization and denitrification; and nitrate, which is highly water-soluble, by leaching).

Human activities that fix nitrogen, such as the manufacture of artificial fertilizers, have had large and unanticipated effects on the nitrogen cycle. The extensive use of artificial fertilizers on agricultural crops, coupled with the burning of fossil fuels (which generates nitric oxide and nitrogen dioxide), has resulted in total nitrogen fixation by humans being nearly equal to global natural nitrogen fixation (see [Figure 57.17](#)). This human-generated nitrogen flux has been increasing over the past half-century and is expected to continue to increase.

One consequence of artificial fertilizer production is an increase in the greenhouse gas nitrous oxide (N_2O), resulting in more tropospheric ozone (O_3) and smog. Tropospheric ozone is itself a greenhouse gas and thus can contribute to global climate change.

Some of the nitrous oxide that enters the atmosphere falls back to land in precipitation or as dry particles. This deposition of nitrogen from the atmosphere has increased dramatically during recent decades. Nitrogen deposition could affect the composition of terrestrial vegetation by favoring those plant species that are best adapted to take advantage of high nutrient levels, and which may then outcompete other species.

Another consequence of nitrogen fertilizers is eutrophication, a process we considered in [Key Concept 57.2](#) for phosphorus additions in lake ecosystems. In this case, when more nitrogen fertilizer is applied to agricultural lands than can be taken up by the crops, the excess nitrogen moves out of the system in surface runoff, or downward into groundwater, and ultimately ends up in rivers, lakes, and oceans. So-called dead zones have formed near the mouth of the Mississippi River in the Gulf of Mexico as a result of the drainage from interior agricultural fields carrying high concentrations of nitrogen fertilizer.

Media Clip 57.1 Tracking Dead Zones from Space www.Life11e.com/mc57.1

The global phosphorus cycle is dominated by geochemical processes

Phosphorus accounts for only about 0.1 percent of Earth's crust, but it is an essential nutrient for all life forms. It is a key component of cell membranes, DNA, RNA, and ATP. Unlike the other biogeochemical cycles discussed thus far, the phosphorus cycle does not have a significant atmospheric component, although some phosphorus is transported by dust particles. Most of Earth's phosphorus is in the form of phosphate in rocks and deep-sea sediments, and it cycles very slowly through the geological system because it requires sedimentary rock formation, uplift, and weathering. In contrast, phosphorus in organisms cycles rapidly, and it is often a limiting factor for their growth, particularly for plants. As you learned in [Key Concept 57.2](#), runoff of phosphorus from fertilizers and detergents into aquatic systems can result in eutrophication.

The burning of fossil fuels affects the sulfur cycle

Sulfur is required by all organisms because it is critical in the production of proteins and lignin. Most of Earth's sulfur supply is locked up in rocks on land and as sulfate salts in deep-sea sediments, but sulfur moves to the atmosphere in a variety of ways. Roughly 10-20 percent of atmospheric sulfur is produced in volcanic eruptions. In terrestrial systems, when sulfur in the soil comes in contact with atmospheric oxygen, it is converted to sulfate salts, which can be taken up by plants and eventually incorporated into their tissue. This sulfur ultimately is returned to the atmosphere as H_2S via microbial decomposition. In marine systems, many phytoplankton and seaweeds manufacture large quantities of a sulfur-containing compound (dimethylsulfoniopropionate, or DMSP) to maintain their salt and water balance. When broken down, DMSP releases dimethyl sulfide (CH_3SCH_3), the principal odorant of rotting seaweed. Because the quantities of phytoplankton in the oceans are enormous, dimethyl sulfide production accounts for about half of the biotic component of the global sulfur cycle.

Atmospheric sulfur exists in gaseous and particulate forms and plays an important role in global climate. Cloud formation is dependent on small particles around which water can condense. Dimethyl sulfide is a major component of such particles, so increases in atmospheric sulfur concentrations increase cloud cover and reduce the amount of incoming solar radiation, affecting Earth's temperature. In addition, SO_2 and NO_2 produced by humans from the burning of coal and oil react with water molecules in the atmosphere to form sulfuric acid (H_2SO_4) and nitric acid (HNO_3), respectively. These acids can travel hundreds of kilometers in the atmosphere before they are released as acid rain. Acid rain can damage forests and lakes, affecting the food webs they support. Restriction on the emissions of sulfur in North America and

Europe has resulted in significant reductions in acid rain. Research shows that once acidity is reduced, forest and aquatic systems can quickly recover. Acid rain remains a problem in some countries such as China and India, where rapid industrialization and the lack of restrictions create high sulfur emissions.

57.4 recap

Nutrient cycling in ecosystems and global biogeochemical cycles involves chemical and biological transformations through both production and decomposition. The hydrologic cycle is not only crucial in making water available to organisms but also in transporting nutrients within ecosystems. Carbon moves through biological systems and returns to the atmosphere through respiration. Burning of fossil fuels increases the carbon dioxide and sulfur in the atmosphere, which is implicated in global warming and acidic conditions in lakes and oceans. The nitrogen cycle is dominated by biotic transformations controlled by bacteria, whereas phosphorus and sulfur cycles are dominated by geochemical processes.

learning outcomes

You should be able to:

- Compare and contrast the roles of different water bodies (rivers, lakes, oceans, glaciers, underground aquifers) in the hydrologic cycle, including approximate residence times of water molecules.
- Describe and evaluate data on the effect of fossil-fuel burning on atmospheric CO₂.
- List the important forms of nitrogen moving through the nitrogen cycle, and explain the importance of microbes in this cycle.
- Describe the basics of the phosphorus cycle, including speed of movement through various parts of the cycle.
- Explain the pools and fluxes of the sulfur cycle, and describe differences in the cycling of sulfur on land and in oceans.

1. The residence time of a water molecule is short in organisms, soil, and rivers and is much longer in lakes, glaciers, and oceans. Why?
2. Why is the concentration of CO₂ rising in the atmosphere and oceans? How does this rise in CO₂ affect climate and ocean chemistry?
3. Explain how the nitrogen cycle is dominated by biological processes whereas the phosphorus and sulfur cycles are dominated by geochemical processes.

As you have seen, biogeochemical cycles are intimately involved in how ecosystems function. Just as human alterations of those cycles are affecting ecosystems worldwide, the resulting changes could have important effects on humans as well.

***connect the concept** Evapotranspiration is the evaporative transfer of heat and water from the surfaces of plants into the atmosphere, which reduces air temperature and increases moisture, as described in [Key Concept 53.3](#) and [Figure 53.10](#)

***connect the concept** Coral bleaching occurs when corals are exposed to warm and/or acidic waters, causing expulsion of their photosynthetic algal symbionts, as described in [Chapter 1](#).

These symbionts can sometimes be reacquired, as described in Investigating Life: Can Corals Reacquire Dinoflagellates Lost to Bleaching in [Chapter 26](#).

57.5 Ecosystems Provide Important Services and Values to Humans

Although it seems obvious today that humans depend on ecosystems for survival, explicit recognition of the services they provide and their value is rather recent. Environmental writers introduced the idea of “natural capital” in the 1940s; it was in 1970 that ecosystems were first said to provide people with a variety of “goods and services.” Here we consider more recent efforts to understand the importance of ecosystems to humans.

focus your learning

Ecosystems provide four types of benefits to humans: provisioning, regulating, supporting, and cultural services.

Alteration of ecosystems for human benefits involves trade-offs that sometimes result in deterioration of ecosystem services.

To develop more sustainable use of ecosystems, the value of ecosystem services must be measured.

Ecosystems services are the benefits people obtain from ecosystems. Ecologists recognize four different categories of services depending on their role in the ecosystem:

ecosystems services Benefits that humans obtain from ecosystems such as natural products, protective and regulating services, and recreational, aesthetic, and spiritual enrichment.

- . *Provisioning services* provide products such as food, clean water, timber, and fiber.
- . *Regulating services* regulate events such as hurricanes, floods, disease outbreaks, and water and air quality.
- . *Supporting services* function in such processes as soil formation, carbon sequestration via net primary production, and nutrient cycling.
- . *Cultural services* provide nonmaterial benefits such as recreational activities and aesthetic and spiritual enrichment.

Most of these benefits are either irreplaceable, or the technology necessary to replace them is prohibitively expensive. For example, fresh drinking water can be provided by desalinating seawater, but only at great cost. The aesthetic, spiritual, and recreational benefits of ecosystems are less tangible, but no less important, and no more easily replaced.

Although humans have been altering ecosystems for millennia, the pace and scope of human alterations to ecosystem services have increased considerably in the past century. For example, the 2005 Millennium Ecosystem Assessment estimated that approximately 60 percent of the ecosystem services identified in its study are being degraded or used unsustainably, including fresh water, wild-caught fisheries, air and water purification, and the regulation of regional and local climate, natural hazards, and pests.

Human alteration of ecosystems has had many positive effects on human health and prosperity, but it necessarily involves trade-offs. Agriculture, for example, feeds and employs huge numbers of people. But the spread of agriculture into marginal lands may degrade soils and compromise the ability of ecosystems to provide clean water, as when overuse of artificial fertilizers results in eutrophication. Extensive use of pesticides controls insect pests, but also reduces populations of pollinators and the services they provide to both crops and native plants.

Similarly, the loss of wetlands and other natural buffers has reduced the ability of ecosystems to regulate flooding and other natural hazards. The damage from the tsunami that hit Indonesia and other Southeast Asian countries in December 2004 was greater in many places than it would have been had the mangrove forests that protect the coast not been cut down and converted to shrimp aquaculture farms. Hurricane Katrina, which struck the U.S. Gulf Coast less than a year later, would not have caused as much flooding in New Orleans had the wetlands surrounding the city been intact. Katrina's devastating effects were due in part to a situation that had been developing for decades.

New Orleans is located on the Mississippi River delta. Much of the city lies below sea level, buffered by dams and levees constructed by the Army Corps of Engineers. The upstream dams that protect New Orleans from flooding also prevent the river from depositing the sediments that have sustained the surrounding delta wetlands for centuries. Oil and natural gas producers have cut thousands of small canals through those wetlands in order to lay pipelines and install drilling rigs, and the extraction of oil and gas from beneath the land has caused it to sink. Increased dredging of shipping lanes and rising sea levels have contributed to a rise in salinity, killing off many of the great cypress tree swamps. These extensive alterations resulted in the loss of more than 80 percent (1.2 million acres) of the delta wetlands between 1930 and 2005. By the time Katrina made landfall, those wetlands could no longer protect New Orleans from flooding. Storm surges raced along the paths carved by canals and shipping lanes to breach the levees, inundating much of the city.

The value of ecosystem services can be measured

Practices that allow us to conserve or enhance ecosystems so as to benefit from specific ecosystem goods and services without compromising others are referred to as [sustainable](#). To develop more sustainable practices, there has been growing interest in determining the economic value of ecosystem services. [Ecosystem values](#) are measures of how important ecosystem services are to people—that is, what they are worth. Placing a value on ecosystem services involves estimating the amount we are willing to pay to preserve or enhance ecosystem services. Ecosystem service valuation involves determining (1) the human drivers of ecosystem change, (2) the ecosystem processes or functions that are affected by those changes, (3) how those processes or functions influence all the goods and services of an ecosystem, and then (4) using a variety of economic and social evaluation tools to value those goods and services ([Figure 57.18](#)). Valuing ecosystem services can be difficult, because while it is relatively easy to place a value on certain goods such as fish or timber, it is harder to value nonmarket services such as the existence of an endangered species or the ability to walk in an old-growth forest. Much of ecosystem service valuation involves determining through public surveys and census data the willingness of people to pay for such nonmarket services.

sustainable Pertaining to the use and management of ecosystems in such a way that humans benefit over the long term from specific ecosystem goods and services without compromising others.

ecosystem values Measures of the economic and biophysical values of ecosystem services to humans.

Figure 57.18 Key Steps to Ecosystem Service Valuation Placing a value on ecosystem services, such as this mangrove ecosystem used for shrimp farming, involves determining (1) the human drivers of ecosystem change, (2) the ecosystem processes or functions affected by those changes, (3) how those processes or functions affect the delivery of goods and services of an ecosystem, and (4) the willingness of people to pay for those goods and services.

For those ecosystems in which services have been valued, in many cases the total economic value of a sustainably managed ecosystem is higher than that of a converted or intensively exploited ecosystem ([Figure 57.19](#)). For example, the value of coastal ecosystems such as mangroves can be driven largely by the coastal protection that mangroves provide from extreme storm or tsunami events, even though the short-term monetary gains from converting mangroves to shrimp farms can be substantial.

Figure 57.19 The Economic Value of Sustainability Managed Ecosystems Many types of ecosystems are able to provide more goods and services, and thus have a higher value, when they are sustainably managed than when they are completely converted to human use.

An important aspect of valuing ecosystem services is changing the impression that ecosystem services are “public goods” with no market value. People who do not stand to profit from the services provided by ecosystems have no incentive to pay for them, whereas individuals who convert ecosystems reap great economic benefits. Government action may be needed to create incentives that encourage sustainable ecosystem management. Raising public awareness is essential to the implementation of sustainable management programs. Most people do not realize the long-term value of ecosystem goods and services or understand how human activities affect the functioning of ecosystems. Maintaining and enhancing ecosystem goods and services that have no established market value is especially difficult. Perhaps one of the most difficult ecosystem services to maintain and value is that of biodiversity. The final chapter of this book is devoted to this important topic.

57.5 recap

Ecosystems provide benefits to humans in the form of goods and services. Ecologists recognize different categories of services depending on their role in the ecosystem. Ecosystem service valuation involves determining the market value or the willingness of people to pay for the services.

learning outcomes

You should be able to:

- List the four types of ecosystem services, explain the meaning of each, and give examples.
- Explain, with examples, the types of trade-offs that occur when humans change ecosystems for their own benefit.
- Define sustainability, and analyze its relationship to ecosystem services.

1. Mangroves provide coastal protection from extreme waves and winds, raw materials such as timber and fibers, erosion control, water purification, habitat for fisheries, carbon sequestration, and tourism, recreation, and education. Place each of these services into the four types of benefit categories.
2. Suppose you want to maximize the coastal protection service of mangroves with shrimp aquaculture farming (which requires removing the mangrove trees to create ponds). What sustainable solution might you devise to maximize the value of this ecosystem?

▶ investigatinglife

QA How will food webs respond to the multiple effects of ocean acidification and warming in marine ecosystems?

Much of the ocean acidification research to date has focused on the responses of single species to increasing CO₂ and warming. While we know that ocean acidification and warming can have negative effects on calcifying organisms, potentially affecting already compromised coral-reef ecosystems, we know much less about the potentially counteracting effects of elevated CO₂ on primary producers and their consumers. Is it possible that organisms, placed within the context of their food webs, gain some resilience from the effects of climate change? The study of a Swedish estuary showed that the response of this ecosystem to ocean acidification and warming is modulated by complex food web interactions. The implications of this study may be wide-ranging if changes in food webs decrease the ability of ecosystems to respond to climate change. Will the loss of top consumers make ecosystems less resilient to climate change? This is a question that needs to be considered as both food webs and global climate change.

Future directions

While the Swedish estuary experiment shows that a consumer can affect an ecosystem's response to climate change, climate change can also affect a consumer's role in an ecosystem. A good example is the recent dramatic shift in polar bear and orca whale observations in the Canadian Arctic. Sea ice in the Arctic is melting at unprecedented rates as the result of global warming. Polar bears need this sea ice to stalk their prey, mainly seals, but have been driven to inland hunting grounds with the loss of ice. Orca whales, by contrast, are unable to hunt their preferred prey, other species of whales, in ice-covered waters. As ice continues to melt, orcas have been spotted in areas of the Arctic where they have never been seen before. Some people have suggested that this shift from seal predation to whale predation could have important ecosystem-level effects as the food webs shift in response to the decline of sea ice.

► 57.1 Ecosystem Science Considers How Energy and Nutrients Flow through Biotic and Abiotic Environments

- **An ecosystem** includes all the organisms in a given area and their physical and chemical environment.
- Energy flowing through ecosystems originates with sunlight and inorganic and organic compounds. It involves the processes of photosynthesis, **chemosynthesis**, and **secondary production**. **Review Focus: Key Figure 57.1, Activity 57.1**
- Energy is lost from ecosystems as metabolic heat.
- Nutrients originate in soil, water, and the atmosphere and cycle through ecosystems via the processes of production and decomposition.

► 57.2 Energy and Nutrients in Ecosystems Are First Captured by Primary Producers

- **Net primary production (NPP)** is the amount of carbon remaining in plants after respiration, and varies with latitude and ecosystem type. **Review Figures 57.2, 57.4**
- Terrestrial NPP is highest in the tropics where temperatures are high year-round and rainfall is abundant. **Review Figures 57.3A, 57.5**
- Oceanic NPP varies little with latitude but peaks at mid-latitudes and in coastal zones and areas of upwelling where the main primary producers-phytoplankton and algae-have access to light and nutrients. **Review Figure 57.3B**
- In aquatic systems, nutrient runoff from agriculture and wastewater can cause **eutrophication**, resulting in algal blooms and low oxygen conditions (hypoxia) for aquatic life.

► 57.3 Food Webs Transfer Energy and Nutrients from Primary Producers to Consumers

- Once energy captured by primary producers is fixed as NPP, consumption by heterotrophs transfers a fraction of that energy to higher trophic levels, creating **net secondary production**. **Review Figure 57.1**
- Organisms differ in their **production efficiency**, or the percentage of energy stored in assimilated food that is used to produce new biomass. **Review Figure 57.8, Table 57.1**
- The amount of energy transferred within food webs depends on **trophic efficiency**, or the amount of energy used at one trophic level divided by the amount used at the trophic level below it. **Review Figure 57.9**
- The flow of energy in food webs is influenced by the number of trophic levels and the relative contribution of bottom-up (NPP passing up the food web) and top-down (consumers regulating NPP) forces. **Review Figure 57.10A**
- Most food webs have just three or four trophic levels because of energy limitations at higher trophic levels, the effects of disturbance, or the evolutionary constraints on top predators.

► 57.4 Nutrient Cycling in Ecosystems Involves Chemical and Biological Transformations

- Nutrients move through the biotic parts of ecosystems via production and **decomposition**. **Review** [Figure 57.11](#)
- At a global scale, nutrients move through geological, atmospheric, and biological pools, making up **biogeochemical cycles**.
- Water cycles rapidly through the globe as part of the hydrologic cycle, transporting nutrients and serving as an essential requirement for organisms. **Review** [Figure 57.12](#), [Animation 57.1](#)
- Carbon moves through biological systems and returns to the atmosphere through respiration. **Review** [Figure 57.13](#), [Animation 57.2](#)
- Burning of fossil fuels increases the carbon dioxide and sulfur in the atmosphere, causing global warming and acidic conditions in oceans and lakes. **Review** [Figures 57.14](#), [57.15](#), [Investigating Life: Food Webs in an Acidic and Warming Ocean](#)
- The nitrogen cycle is dominated by biotic transformations controlled by bacteria, whereas the phosphorus and sulfur cycles are dominated by geochemical processes. **Review** [Figures 57.16](#), [57.17](#), [Animation 57.3](#)

► 57.5 Ecosystems Provide Important Services and Values to Humans

- **Ecosystem services** benefit humans and can be categorized as those that provide provisioning, regulating, supporting, or cultural services.
- Most ecosystem services are either irreplaceable or prohibitively expensive to replace.
- **Ecosystem values** are measures of how important ecosystem services are to people—that is, what they are worth. **Review** [Figure 57.18](#)
- Ecosystem services can be valued by determining the market value or the willingness of people to pay for the services. **Review** [Figure 57.19](#)

see Activity 57.2 for a concept review of this chapter.

Original Paper: Slater, M. J. and A. G. Carton. 2009. Effect of sea cucumber (*Australostichopus mollis*) grazing on coastal sediments impacted by mussel farm deposition. *Marine Pollution Bulletin* 58: 1123-1129.

Some coastal marine ecosystems receive excess organic matter from aquaculture farms. This can concentrate organic matter in the sediment and decrease oxygen, leading to hypoxia. Scientists believe that benthic organisms, such as sea cucumbers, might help mitigate this potentially detrimental effect. Sea cucumbers feed on sediments containing bacteria, benthic marine algae, and the feces of cultured species; thus they recycle organic matter and alter nutrient fluxes in the ecosystem. They also disturb sediments, causing some amount of mixing with the water column above.

Researchers studied the effects of sea cucumber grazing on the chemistry of sediments produced by cultured mussels, filter feeders on phytoplankton. The researchers set up 16 experimental tanks with flowing filtered seawater. Three tanks were maintained as controls, with no grazing, and one tank was kept as a water filtration control. Each of the other 12 tanks housed a single sea cucumber, which was fed a specific amount of mussel-farm sediment daily. The experiment was run for four grazing periods that lasted 1, 2, 4, and 8 weeks. Chemical tests were run on the sediments at the end of each grazing period.

The graph shows the results of tests for total organic carbon (TOC). TOC measures all organic carbon including live and dead matter and not including CO₂ released from metabolism. It is sometimes used to measure organic pollution from sewage or agriculture.

Questions

- How would you describe the position of sea cucumbers in the marine benthic food web? How might their position affect net primary production (NPP) through this ecosystem?
- Based on the graph, what can you conclude about the effect of sea cucumbers on the amount of TOC in sediments? How is this effect related to nutrient cycling?
- Why do you think TOC (see graph) continues to increase over the course of the experiment? How does this increase relate to the activities of sea cucumbers?
- A major problem in aquaculture operations such as mussel farming is hypoxia, or dangerously low levels of oxygen in the water. Given the information on TOC in this experiment, how do you think oxygen levels likely changed over the course of the experiment? What factors would cause these changes, and how does the presence of sea cucumbers affect the likelihood of hypoxia?
- An aquaculture manager cultures mussels in a coastal farm. He has a serious pollution problem, due to the waste his mussels release into the water, and the resulting hypoxia. He is considering whether to introduce sea cucumbers into his farm. What ecological trade-offs occurred when the mussel farm was first developed? Would the addition of sea cucumbers into the system be considered an ecosystem service? Explain your answer.

A Changing Biosphere

A small population of the harlequin toad (*Atelopus varius*), a species in Costa Rica that was presumed extinct in 1996, was found in a mountainous protected area in 2003.

key concepts

[58.1 Human Activities Are Changing the Biosphere, Resulting in Biodiversity Loss](#)

[58.2 Most Biodiversity Loss to Date Is Caused by Habitat Loss and Degradation](#)

[58.3 Protecting Biodiversity Requires Conservation and Management Strategies](#)

Fatal Fungus Final Fate for Frogs?

Most of us have at some point in our life encountered a frog in a local pond or park. Maybe more than almost any other wild animals, amphibians are commonly encountered by human beings. But since the late 1980s, ecologists have documented a sharp global decline in amphibian species- more than in any other major taxonomic group on Earth. Some regions show greater declines than others, but since 1980, 33 species of amphibians have become extinct, with an additional 115 species “missing in action” (not seen since that time) and 848 species in danger of extinction. A study by the International Union for Conservation of Nature (IUCN) showed that amphibians are more threatened than either birds or mammals, with 31 percent of amphibian species (1,994) being globally threatened and 37 percent (2,394) experiencing some type of population decline.

The decline has been particularly worrisome to scientists for a few key reasons: the sudden and global nature of the decline, the undisturbed nature of the areas where some the declines have occurred (for example, mountainous rainforest preserves in Costa Rica, where 40% of the amphibians have become extinct), and the reputation of amphibians as “biological indicators” of environmental conditions. Amphibians have permeable skin, live their lives in water and on land, and typically do not move long distances, factors that make them particularly susceptible to changes in their immediate environment. The IUCN study showed that most amphibian declines were caused by habitat loss, habitat degradation, and overexploitation, but for 48 percent of the rapidly declining species, there was no clear explanation. What factors might be contributing to the rapid decline of these species?

Over the last two decades, a highly lethal and infectious skin disease called chytridiomycosis, caused by a fungal pathogen (*Batrachochytrium dendrobatidis*), has been linked to mass mortalities of amphibians, especially in the regions where amphibian declines have been most dramatic. The disease was first discovered in 1993 in dead frogs in Australia and then seemed to appear suddenly in the Americas, Africa, Europe, and New Zealand. However, it is not clear how or why the fungal disease has emerged as a threat, and whether humans have contributed to its spread. An increasing number of studies are looking for reasons why this deadly disease has emerged and how it might be prevented.

QA Is the most recent dramatic decline of amphibians the result of a novel fungal pathogen, and if so, what can be done about it?

58.1 Human Activities Are Changing the Biosphere, Resulting in Biodiversity Loss

Throughout [Part Ten](#) we have described the dramatic ways in which the biosphere is changing as a result of human activities. The causes of these changes have been varied, and include habitat destruction and degradation, overharvesting of species, species invasions and emerging diseases, and now climate change. One of the largest ecological consequences of these changes has been the rapid decline of biodiversity, or the loss of diversity at genetic, population, species, ecosystem, and global scales.

focus your learning

Various factors decrease effective population size, eventually leading to extinction.

Biodiversity connects species at all levels; its loss affects population, metapopulation, species, ecosystem, and global levels.

It is very difficult to track and predict extinctions.

Biodiversity has great value to human society

The escalating loss of Earth's biodiversity is of great concern for many reasons:

Humans depend on thousands of species and their ecosystems for ecosystem goods and services. As you learned in [Key Concept 57.5](#), species and eco-systems provide humans with important goods (e.g., food, timber, and fiber) and services (e.g., regulating and supporting services such as coastal protection, water and air quality, soil formation, and carbon sequestration).

Humans derive enormous psychological benefits, including aesthetic pleasure, from interacting with other organisms. These aesthetic benefits are the reason we surround ourselves with parks and recreate in the wilderness.

Living in ways that cause the extinction of other species raises ethical issues. Loss of biodiversity is of concern to anyone who believes humans have an ethical obligation to the natural world.

Extinctions deprive the public and scientific community of opportunities to study and understand ecological relationships among organisms. The more species that are lost, the more difficult it will be to understand the biosphere as it exists today.

Recognizing the importance of biodiversity propels us to develop strategies for protecting and managing it and has spawned the development of [conservation biology](#)—an integrative scientific discipline that relies on principles of ecology, economics, social science, and policy to protect and manage Earth's biodiversity. As you will see, we will refer to many ecological concepts from other chapters to establish, first, how and why biodiversity is being lost and, second, the role of conservation biology in protecting against and managing its further loss.

conservation biology An integrative scientific discipline that relies on principles of ecology, economics, social science, and policy to protect and manage Earth's biodiversity.

Diversity loss at one scale affects diversity loss at other scales

As you have seen in [Key Concept 56.1](#), biodiversity is central to the interconnectedness of various levels of biological organization, from genes to species to communities. Thus the loss of diversity at one scale affects the loss of diversity at other scales ([Figure 58.1](#)). For example, when human-caused activities reduce the number of individuals in a population, they reduce what is called the [effective population size](#), or the number of individuals that can contribute offspring to the next generation (**Focus: Key Figure 58.2**), resulting in further population size decline, or what has been termed an “extinction vortex.” How does the effective population size continue to decline? First, small populations are more likely to experience [*genetic drift](#) and inbreeding, which can lead to reduced genetic diversity and [inbreeding depression](#). Second, when population sizes are small, there is also a greater chance of [demographic stochasticity](#), or fluctuations in population size as the result of random differences among individuals in reproduction and survival. For example, a small population might have, by chance, fewer females than males, resulting in fewer offspring than expected if the sex ratio were reversed. Finally, external mortality events such as extreme weather or habitat destruction can have devastating effects on small populations by increasing their chance of extinction even if only a small number of individuals are killed.

Human-caused habitat destruction, overharvesting, species invasions and emerging diseases, and climate change cause the loss of individuals...

...leading to smaller and less genetically diverse populations, which are more susceptible to extinction (see Figure 58.2). The fewer populations there are, the smaller the metapopulations and the greater the risk of species extinction.

Once species are lost, species diversity can decline if those species play critical roles in the ecosystem.

Declines in species diversity in ecosystems lead to losses at regional, continental...

...and global scales.

Figure 58.1 Biodiversity Loss Is Interconnected across Scales Human activities have caused the rapid decline of biodiversity, or the loss of diversity at genetic, population, species, ecosystem, and global scales. Implicit in biodiversity loss is the concept that the loss of diversity at one scale affects the loss of diversity at other scales (see [Figure 56.5](#)).

effective population size The number of individuals within a population that can contribute offspring to the next generation of the population.

demographic stochasticity Fluctuations in population size as the result of random differences among individuals in reproduction and survival.

 **focus:** key figure

Figure 58.2 Extinction Vortex Human-caused and natural events can reduce the effective population size (number of individuals that can contribute offspring to the next generation) of species, eventually leading to population and species extinctions.

Q: Explain how the chytrid fungal pathogen described in the opening story could cause the

Biodiversity loss is also connected at higher metapopulation, species, and ecosystem levels (see [Figure 58.1](#)). For example, you know from [Key Concept 54.4](#) that the larger the metapopulation, the greater the chance that dispersal among source populations can rescue sink populations from extinction. As more local populations become extinct, and as more metapopulations are compro-mised, there is a greater risk that species will become extinct as well. Unfortunately, if some of those species play critical roles in their ecosystems—if they are, for example, keystone or foundation species—the possibility exists that other species will be threatened with extinction as well. As species diversity declines in ecosystems, biodiversity loss manifests itself at larger regional, continental, and even global scales (see [Figure 58.1](#)).

There are many examples of how a series of unfortunate events at different levels of biodiversity has led to the extinction of species (or subspecies, in the case below). Consider the heath hen (*Tympanuchus cupido cupido*), a large bird in the grouse family ([Figure 58.3A](#)). Heath hens were common from Maine to Virginia prior to the 1800s but were hunted extensively for food. By 1830 only one population, on the island of Martha's Vineyard, Massachusetts, was left. By 1908 only 50 birds remained, and a reserve was established to recover the population, which eventually grew to several thousand birds. Unfortunately, in 1916 a fire and a series of environmental factors that included a hard winter, an influx of predators, and a poultry disease caused the population size to decline dramatically. By 1928 demographic stochasticity and inbreeding depression set in, leaving only 13 individuals—2 females and 11 males. Four years later, the heath hen was extinct.

(A)

Tympanuchus cupido cupido

Tarsius pumilus

(B)

Figure 58.3 Species Extinctions: Going, Going ... (A) The heath hen (left) became extinct in 1932. In 2008 the pygmy tarsier (right) was discovered in an Indonesian national park after having been presumed extinct for 85 years. **(B)** The pie chart shows the breakdown by extinction risk category of 59,033 species assessed by the International Union for Conservation of Nature. The bar graph shows the number of species in the various extinction risk categories (three of which are together termed “threatened”) in taxonomic groups that have been comprehensively assessed.

Q: What percentage of species are extinct versus threatened with extinction? Of those species, which taxonomic group has experienced the most extinction and which is most at risk of extinction?

Species diversity is being lost at unprecedented rates

The loss of the heath hen and other extirpations caused by humans (see [Figure 58.3](#)) remind us of the finality inherent in species extinctions. However, over the scope of Earth’s history extinction has been a constant theme; most of the species that have lived on Earth are extinct today. Extinctions have occurred throughout Earth’s history at what is referred to as a “background” rate as changes in environmental conditions have favored some species and negatively affected others. But the rate of extinctions taking place today rivals those of the five great mass extinction events, which were the result of cataclysmic natural disturbances rather than human activities (see [Table 24.1](#) and [Figure 24.2](#)). One estimate, from renowned evolutionary biologist Edward O. Wilson suggests that Earth is losing some 30,000 species per year, putting us in the midst of a sixth mass extinction event.

This mass extinction event has been ongoing for some time. For example, research suggests that when humans first arrived in North America from Siberia about 14,000 years ago, they encountered a diverse and spectacular group of large mammals, including saber-toothed cats, dire wolves, mammoths, mastodons, giant ground sloths, and giant beavers. Most of this “megafauna” became extinct within a few thousand years after humans arrived. Although several hypotheses have been advanced to account for the rapid and simultaneous disappearance of so many large animals, overhunting by humans is the most likely explanation. Losses of megafauna coinciding with the arrival of humans have been documented worldwide, most notably in Australia, New Zealand, and Madagascar. Tracking and predicting extinctions are, however, difficult for several reasons:

We do not know how many species live on Earth today. Many species that are likely to become extinct in the near future have not been named and described by scientists. Insects provide a case in point: although more than 1 million species have been described (see [Key Concept 31.4](#)), estimates of the number of species yet to be discovered range from 2 million to more than 50 million. Even for larger organisms, our understanding of diversity is incomplete. For example, worldwide, an annual inventory of newly described species reported 19,232 species discovered in 2009 alone; this list included 9,738 insects, 2,184 plants, 1,360 fungi, 71 mammals, and 7 birds.

The distributions of most described species, particularly those that are small, reclusive, and rare, are poorly known. One tiny North American true bug, *Corixidea major* (so rare it has no common name), had been found in only one location near Clarksville, Tennessee, until entomologists using lights to collect insects at night discovered it in Virginia and Florida, extending the species’ known range by more than 1,000 kilometers.

It is difficult to determine whether a species is truly extinct. Rarely is the death of the last surviving member of a species recorded with certainty, as it was in the case of the last passenger pigeon (*Ectopistes migratorius*), a female named Martha, that died in the Cincinnati

Zoo on September 1, 1914. The status of rare, reclusive species with poorly known life histories is much more difficult to determine, as has been the case with the pygmy tarsier (*Tarsius pumilus*) (see [Figure 58.3A](#)). This tiny primate, weighing less than 60 grams, was thought to have become extinct in its native cloud forests on the island of Sulawesi in Indonesia. In 2008—85 years after the last reported sighting of a living *T. pumilus*—a research team discovered individuals of this species living in one of the island's national parks.

We rarely know all of the interactions among species. The loss of one species—be it as a member of a food web or as habitat for species—can place other species at risk. How many species are at risk as a result of their interactions with other species is hard to characterize and often requires detailed ecological knowledge.

Media clip 58.1 **New Species Found in the Twenty-First Century**
www.Life11e.com/mc58.1

We can predict the effects of human activities on biodiversity

Despite gaps in our understanding of biodiversity, methods exist for estimating the extinction probability of species, taking into account their population sizes, genetic variation, life history traits, and ecology. The IUCN has published categories that define the risk of extinction of species. Species in imminent danger of extinction in all or most of their range are classified as “critically endangered” or “endangered”; those believed to be susceptible to extinction in the near future are classified as “vulnerable.” Biologists consider species in any one of these three categories to be “threatened” ([Figure 58.3B](#)).

Rarity in and of itself is not always a cause for concern. Some species may be specialized for rare and unusual habitats and not be particularly abundant by nature. But as you saw earlier, “newly rare” species are of concern because large and rapid reductions in population sizes can lead to smaller effective population sizes through a variety of mechanisms (see [Figure 58.2](#)).

Certain aspects of species' life histories can be important in predicting the ability of species to recover from declines (see [Key Concept 54.3](#)). In fishes and mammals, for example, one of the best predictors of extinction risk is age at maturity, a life history trait that influences the rate of reproduction. Ecological requirements can also influence the ability of species to recover from rapid declines. Species with specialized habitat or dietary requirements, for example, are more likely to become extinct than species with more generalized requirements.

Ecologists can apply the principles of the species-area relationship and the theory of island biogeography (see [Key Concept 53.5](#)) to predict the effects of habitat loss on species—a major cause of extinction today. By measuring the rate at which species richness decreases with decreasing habitat patch size, they can estimate how many species that live in and depend on that habitat may be lost. We examined the connection between habitat area and species loss in *Investigating Life: The Largest Experiment on Earth* in [Chapter 53](#).

58.1 recap

Biodiversity has great value to human society in the form of goods and services. Human activities have resulted in a rapid loss of biodiversity, a decline detectable at genetic, population, species, ecosystem, and global scales. Species extinctions can occur when human and natural events reduce effective population sizes and cause inbreeding depression, genetic drift, and demographic stochasticity. Methods exist for estimating the extinction probability of species that take into account their population sizes, genetic variation, life history traits, and ecology.

learning outcomes

You should be able to:

- List major factors causing declines in biodiversity.
- Explain the concept of effective population size; use examples to explain how small population sizes can lead to population and species extinctions.
- Discuss, with examples, why it is difficult to determine the extinction rate of species.

-
1. Define biodiversity loss, and list four reasons for its loss.
 2. Using the extinction vortex concept as your guide, describe how the heath hen became extinct in 1932.
 3. Why is it difficult to determine how many species are extinct or threatened with extinction?
-

We've said that human activities have played a major role in the loss of biodiversity. In the next section we will describe the types of human activities that most threaten biodiversity.

***connect the concepts** As described in [Key Concept 12.3](#), inbreeding depression is a state of reduced biological fitness in a population arising from mating among close relatives that tend to have the same recessive, sometimes deleterious, alleles. [Key Concept 21.2](#) describes how in small populations, genetic drift—random changes in allele frequencies from one generation to the next—may produce large changes in allele frequencies over time. Harmful alleles may increase in frequency, and rare advantageous alleles may be lost.

58.2 Most Biodiversity Loss Is Caused by Habitat Loss and Degradation

Global Biodiversity Outlook 4, a report published by the United Nations in 2014, identified four principal pressures on biodiversity: (1) habitat loss and degradation, (2) overharvesting of biological resources, (3) species invasions and emerging diseases, and (4) climate change. Here we consider each of these pressures separately while keeping in mind that the threats to biodiversity are often not mutually exclusive.

focus your learning

Human-caused habitat loss and degradation are the major causes of biodiversity loss.

Overharvesting of single species for resources has been and still is an important cause of extinction or species decline.

Introduction of non-native species has increased exponentially in the last 200 years, and some introduced species become invasive, usually with negative consequences.

Climate change is affecting species through changes in distribution, timing of life history events, and decreased growth and reproduction.

Habitat loss and degradation endanger species

Most scientists agree that, up to this point in human history, [habitat loss](#) (reduction in habitat quantity) and [habitat degradation](#) (reduction in habitat quality) have been the major culprits in biodiversity loss. Our human footprint is large—it is estimated that we have transformed 50%-60% of the land surface, primarily for agriculture, timber, and livestock grazing. The building of infrastructure, such as cities, transportation corridors, and utilities (including hydroelectric dams) has altered another 2%-3% of Earth's surface.

habitat loss The conversion of an ecosystem by human activities that reduces habitat quantity. (Compare with habitat degradation.)

habitat degradation The conversion of an ecosystem by human activities that reduces habitat quality. (Compare with habitat loss.)

As humans increasingly dominate the planet, the transformations they are causing affect whole biomes and the species dependent on them. For example, the current rate of loss of tropical rainforest — Earth's most species-rich biome — is about 2 percent of the remaining forest each year due to the increasing demands of a rapidly expanding human population for forest products and cleared agricultural land. Most of the rainforests of Asia have already been reduced to small fragments, with the only extensive remaining tracts being found on the islands of New Guinea and, to a much lesser extent, Borneo ([Figure 58.4](#)). As of 2016, the greatest amount of tropical rainforest deforestation had taken place in Brazil. If the current rate of loss continues, millions of rainforest species could become extinct before the end of this century.

Figure 58.4 The Disappearing Tropical Forest Rainforests, the most abundant tropical forests, have long been recognized as centers of biodiversity that harbor vast numbers of species (see rainforest biome, p. 1154). Since the 1950s, tropical forests have been cleared for agriculture, highways, timber resources, and other needs of an exploding human population.

Physical destruction of habitat, as when tropical rainforests are cut down or wetlands are drained and converted to agricultural use, has significant effects on the distributions and abundances of species. Reductions in suitable habitat have contributed to the extinction of thousands of species. As the remaining habitat gets divided into smaller and smaller fragments, it can become further degraded by edge effects (as you saw in Investigating Life: The Largest Experiment on Earth in [Chapter 53](#) and Animation 53.4, Edge Effects). Recall that as habitat fragments become smaller, proportionally more land is exposed to edge effects (see [Key Concept 53.5](#)). The physical conditions at the edges of habitats often are more similar to those of the new habitat than to the original habitat, and this can be physically stressful for species acclimated to the original habitat. In addition, species from surrounding habitats can colonize the edges, where they may compete with or prey on the species living in the fragment.

One effect of forest fragmentation in much of North America has been an increase in the abundance of the brown-headed cowbird (*Molothrus ater*), a brood parasite that lays its eggs in the nests of other bird species. Nestlings of a brood parasite are raised by the host parents, to the detriment of their own young ([Figure 58.5A](#)). Historically, cowbirds followed bison and other grazing mammals, feeding on insects kicked up by the herds; thus their eggs were laid primarily in nests of grassland host species. Forest fragmentation has opened up new opportunities for the cowbirds, which can now lay their eggs in the nests of forest birds in habitat edges, affecting nestling mortality and fledgling success ([Figure 58.5B](#)). Fragmented forests, with relatively more edge than intact forest, thus favor the proliferation of cowbirds at the expense of forest birds.

(A)**(B)**

Figure 58.5 Cowbird Parasitism at Forest Edges **(A)** Cowbirds are nest parasites—they lay their eggs (black speckled) in the nests of host bird species and depend on them to raise their young (note the large cowbird chick). **(B)** At forest edges, host birds have higher nestling loss and lower fledging success as a result of cowbird parasitism.

Pollution is another cause of habitat loss and degradation. The negative effects of acid rain (see [Key Concept 57.4](#)), for example, have greatly affected lake and forest ecosystems. Among the most troublesome toxic pollutants in ecosystems today are heavy metal waste products of mining and manufacturing, and synthetic organic chemicals (pesticides) released into the environment to control pests. Multiple studies have implicated a variety of pesticides in the decline of amphibian species, particularly in areas with intense agriculture such as California and the midwestern United States.

A relatively hidden form of pollution comes from nondegradable plastic garbage in open ocean habitats ([Figure 58.6](#)). One garbage patch in the middle of the Pacific Ocean is estimated to be the size of Texas. Plastic is broken up into smaller pieces and when ingested by marine birds, mammals, or fish can be a choking hazard or disrupt endocrine functions such as reproduction, neural development, and immune function. Plastic or abandoned fishing nets can also entangle marine organisms, including marine mammals, resulting in death.

Figure 58.6 Plastic Ocean Large amounts of plastic garbage have accumulated in the North Pacific Gyre, degrading the pelagic environment. Inset is a photo of tiny bits of plastic comingled with a sample of water taken from the vicinity of the North Pacific Gyre garbage patch.

Overharvesting has driven many species to extinction and changed food webs

Overharvesting occurs when single species, or groups of similar species, are harvested for human use. Overharvesting for such resources as food, clothing, ornamentation, pets, and medicines was once the most important and rapid cause of species extinction. For example, it has been estimated that overharvesting is responsible for roughly 40 percent of the approximately 150 bird species that have become extinct since the 1500s. Maybe one of the most egregious examples of overharvesting of birds came from “plume hunting” in the late nineteenth century. Feathers were harvested for ornamentation on hats and clothing — during the heyday, 5 million birds were killed each year, including 95 percent of Florida’s shorebirds. The plumes of white egrets sold for \$32 per ounce in 1915, which was the same price as gold.

Even today, overharvesting is still of great concern for critically endangered species that are not yet extinct but have a high probability of becoming so within the century, particularly as their habitat declines or is further degraded. Recently there has been an alarming uptick in illegal poaching of what might be considered charismatic megafauna, or species with widespread popular appeal. One example is the illegal poaching of elephants and rhinoceroses in much of Africa and Asia because of markets for ivory tusks and horns. A recent study estimated that in central Africa alone, regional elephant population sizes have declined by 64 percent because of illegal killing within the last decade ([Figure 58.7](#)). On a continental scale, the study showed that between 2010 and 2012, 40,000 elephants were killed illegally, a rate of 8 percent per year.

Figure 58.7 Mass Killing of Elephants One of the largest known mass elephant killing events took place in Bouba Njida National Park, Cameroon, in 2012. Poachers killed more than 300 elephants with AK-47s and grenades.

Massive and lucrative international trade in exotic pets such as birds, nonavian reptiles, frogs, mammals, aquarium fishes and corals, and ornamental plants threatens many species. It is estimated that 2-5 million birds and 2-3 million non-avian reptiles are captured live each year. In addition, it has been estimated that more than 1 billion ornamental fish comprising more than 4,000 freshwater and 1,400 marine species are traded internationally each year. For example, the Banggai cardinalfish (*Pterapogon kauderni*) is on the brink of extinction entirely because of the pet trade; almost a million of these critically endangered fish are caught annually near Sulawesi, Indonesia, to satisfy the demand from saltwater aquarium enthusiasts. The exotic pet trade is worrisome from multiple aspects — harvesting and transporting species not only cause the decline of rare or endangered species but can unintentionally lead to disease transmission or species invasions, as you saw with the lionfishes example in [Chapter 55](#).

Even though we tend to think of the oceans as boundless, they too are affected by overharvesting. Burgeoning human populations in need of food are placing unprecedented pressure on species harvested from the wild. Humans have fished for at least 40,000 years, but in recent centuries innovations in technology and increasing demand have accelerated overharvesting. A recent comprehensive study of fisheries found that nearly 14 percent of fished taxa collapsed between 1950 and 2007 ([Figure 58.8A](#)). The effects of fish harvesting vary widely across the globe, in part because restrictions in some locations have been implemented to encourage the recovery of overfished species ([Figure 58.8B](#)). Top predators such as sharks, bluefin tuna, and groupers, which are preferentially harvested, are at particular risk of extinction. These long-lived species show slow population recovery, and because they are keystone species, their losses are likely to have more lasting ecosystem ramifications.

Figure 58.8 Overharvesting Has Caused Fisheries Collapses, but Some Recovery Is Occurring (A) The number of collapsed fished taxa (estimated as a decline of biomass of the fished taxa to less than 10% of their unfished biomass) increased steadily from 1950 to 2007. **(B)** Worldwide status of exploited fish populations.

Q: Using the map, indicate which regions of the world are experiencing the highest fisheries exploitation.

What are some of the consequences of single-species overharvesting, particularly of species that are long-lived or top predators? First, species such as elephants and rhinoceroses that are characterized by slow population growth show slower recovery. Blue whales are at greater risk of extinction than are humpbacks, even though both species experienced chronic overharvesting in the nineteenth century. You saw in [Key Concept 54.4](#) that while humpback whales have been recovering relatively quickly with the cessation of hunting, blue whale populations have lagged behind because of their lower reproductive rates. Recovery of populations of the black rockfish (*Sebastes melanops*), which we introduced in [Key Concept 54.4](#), has been extremely slow because older, larger females were preferentially harvested, and the remaining smaller females produce fewer and smaller larvae.

Second, consider what happens when an overharvested species plays an important keystone or foundation role in its community. A recent study by William Ripple and colleagues considered the status and ecological consequences of the decline of 31 of the world's largest carnivores. Most of the species studied have experienced substantial population declines over the past two centuries as the result of overharvesting, persecution (culling because of conflicts with humans), and habitat loss. Using data from several studies, the researchers showed that when top large carnivores declined, trophic cascades were interrupted, dramatically changing the abundance of herbivore and primary producer species ([Figure 58.9](#)). This research suggests that large carnivores are necessary to maintain biodiversity and ecosystem function in some ecosystems.

Figure 58.9 Large Carnivores Are Declining, Changing Food Webs Examples of the effects of large- carnivore decline on the change in abundance of species in their food webs. The blue bars represent the direct effects and the red bars represent the indirect effects. The number of years refers to the time since the carnivore species ceased to exist at the study site.

Invasive predators, competitors, and pathogens threaten many species

Deliberate or inadvertent introductions of non-native species have increased exponentially over the last 200 years. It is estimated that 50,000 species have been introduced to the United States alone. Many of these species were intentionally introduced to provide food, natural resources, or other important services for humans. But roughly 10 percent of these species have become **invasive**—that is, they reproduce rapidly, spread widely, and have mostly negative effects on the native species or ecosystems of the region. As you saw in [Key Concept 56.2](#), once an introduced species arrives in a new community, a successful invasion usually involves multiple introduction events and the ability to cope with the physical environment and coexist with other species in the community.

invasive species A non-native species that reproduces rapidly, spreads widely, and has mostly negative effects on the native species or ecosystems of the region to which it has been introduced.

While arguments can be made for the positive side of some species invasions, most invasions have had negative effects on species and ecosystems. For example, estimates suggest that 400 of the 958 species (42%) listed under the U.S. Endangered Species Act are at risk primarily because of predation, competition, or disease transmission by invasive species. Invasive species also can have dramatic effects on the functions and services of ecosystems, affecting

fire cycles, water availability, and coastal sedimentation ([Figure 58.10](#)). Invasive species have even changed the genetic diversity of native species through hybridization events with wild populations (e.g., non-native rainbow trout and native cutthroat trout in Montana). The total cost estimate for dealing with undesirable invasive species in the United States alone was roughly \$120 billion per year.

Figure 58.10 Species Invasions Can Change Ecosystem habitat Functions and Services Three examples of the effects that invasive species can have: **(A)** cheatgrass increases the fire cycle in sagebrush habitat, **(B)** salt cedar draws down water in desert streams, and **(C)** English cordgrass leads to sedimentation, transforming coastal mudflats into salt marshes.

Non-native species are spread in a variety of ways. Over the past 400 years, Europeans colonizing new continents have deliberately introduced plants and animals to reconstruct their once familiar surroundings. Many of these introductions have had disastrous effects on native flora and fauna. In Australia the introduction of European rabbits and foxes for sport hunting and of dogs and cats as pets has led to the extermination of nearly half the small to medium-sized native marsupials over the last 100 years. As you saw in [Key Concept 54.4](#), the use of biological control, or the deliberate introduction of species to control other invasive species, can sometimes cause even greater problems. Examples include the introduction of small predators such as mongoose to Hawaii to control rabbits and stoat (a type of weasel) to New Zealand to control rats. Instead of curbing the population sizes of rabbits and rats, these predators have been the major cause of bird species extinctions on these islands.

Sometimes invasions have occurred out of ignorance in what people believe are unlikely events of releasing non-native species (as was the case with the lionfishes described in [Chapter 55](#)). It can be difficult for people to imagine that species that are desirable and attractive in their place of origin can “go rogue” in a new region. Some of today’s most noxious weeds were deliberately transported and planted in new places for their beauty, fragrance, or culinary value.

A more inadvertent mechanism of introduction comes from species that stow away during transportation. For example, you saw how non-native species can be transported in ballast water in [Key Concept 56.2](#). The brown tree snake (*Boiga irregularis*) arrived on Guam in air cargo shortly after World War II and today can be found at densities up to 5,000 individuals per square kilometer. The snake has exterminated 15 species of land birds, including 3 found only on Guam.

Introduced pathogens have also wreaked havoc among native species, as exemplified by the

fungal pathogen *Batrachochytrium dendrobatidis*, or Bd for short, which is implicated in the dramatic worldwide declines of amphibians over the last 20 years. As described in the story opening this chapter, the disease may be responsible for the large percentage of amphibian declines recorded globally and for which there has been no clear explanation (the others being a result of some combination of habitat loss, overharvesting, exposure to UV radiation, or pollution). Such “rapidly declining” events have taken place on all the major continents and occur within well-protected areas such as Yosemite National Park (USA), Monteverde Cloud Forest Reserve (Costa Rica), and Eungella National Park (Australia). Most of the mass mortality events in which Bd has been implicated have not been observed because they happen so rapidly. Generally, researchers return to a site to find that population sizes are drastically reduced, or that some species are missing altogether, and discover the fungus present in some remaining individuals.

Researchers studying amphibian declines are interested in whether Bd is a novel and highly virulent pathogen that was recently introduced into wild populations (“novel pathogen hypothesis”) or if Bd existed prior to the declines but emerged as a serious pathogen as a result of human-caused environmental changes to climate or UV radiation (“emerging endemic hypothesis”). Although Bd seems to thrive under fairly specific environmental conditions (high-elevation streams with permanent water sources and temperatures between 12°C and 27°C), most of the evidence now suggests that Bd is a non-native pathogen likely introduced through the global trade in amphibians for food, for use as laboratory animals, or for use as pets or display animals. **Investigating Life: Exploring the Decline of Central American Frogs** describes research by Karen Lips and colleagues on the 20-year decline of four species of frogs in the genus *Atelopus* at multiple sites in Costa Rica and Panama. Their data suggest that the Bd pathogen traveled as an “invasion front” from infected to uninfected populations over time and that, based on microscopic tissue analyses of frogs collected prior to the declines, Bd was probably never present in this region of the world until its introduction in the 1980s. Of the four *Atelopus* species considered in this study, three species (*A. chiriquiensis*, *A. senex*, and *A. zeteki*) are likely extinct, and one species (*A. varius*; photo at chapter opening), thought to be extinct in 1996, likely exists only in a small population near Quepos, Costa Rica.

Exploring the Decline of Central American Frogs

experiment

Original Paper: Lips, K., J. Diffendorf, J. Mendelson and M. Sears. 2006. Fading the wave: Reconciling the roles of disease and climate change in amphibian decline. *PLoS Biology* 6: e72.

Karen Lips and her colleagues studied the spread of the fungal pathogen *Batrachochytrium dendrobatidis* (*Bd*), implicated in the dramatic declines of frogs in the genus *Atelopus* seen in the moist and mountainous regions of lower Central America (Costa Rica and Panama) starting in the late 1980s. They compiled biogeographic reports of *Atelopus* declines and conducted microscopic tissue analyses to test whether *Bd* was a non-native pathogen species recently introduced to Central America or an existing disease that emerged as the result of changes in climate or the environment.

HYPOTHESIS Amphibian declines in Central America are caused by the non-native species invasion of the *Bd* pathogen rather than an environmentally induced emergence of *Bd* as an existing pathogen.

METHOD

1. The researchers mapped the location and approximate year of decline as a result of *Bd* infection for populations of four species of *Atelopus* at numerous sites in Costa Rica and Panama using data from
